Development of a comprehensive protein microarray for immunoglobulin E profiling in horses with severe asthma

Samuel White, Meriel Moore-Colyer, Eliane Marti, Laurent Couetil, Duncan Hannant, Eric A. Richard, Marcos Alcocer

Abstract

Background: Severe asthma in horses, known as severe equine asthma (SEA), is a prevalent, performance-limiting disease associated with increased allergen-specific immunoglobulin E (IgE) against a range of environmental aeroallergens.

Objective: To develop a protein microarray platform to profile IgE against a range of proven and novel environmental proteins in SEA-affected horses.

Animals: Six SEA-affected and 6 clinically healthy Warmblood performance horses.

Methods: Developed a protein microarray (n = 384) using protein extracts and purified proteins from a large number of families including pollen, bacteria, fungi, and arthropods associated with the horses, environment. Conditions were optimized and assessed for printing, incubation, immunolabeling, biological fluid source, concentration techniques, reproducibility, and specificity.

Results: This method identified a number of novel allergens, while also identifying an association between SEA and pollen sensitization. Immunolabeling methods confirmed the accuracy of a commercially available mouse anti-horse IgE 3H10 source ($R^2 = 0.91$). Biological fluid source evaluation indicated that sera and bronchoalveolar lavage fluid (BALF) yielded the same specific IgE profile (average $R^2 = 0.75$). Amicon centrifugal filters were found to be the most efficient technique for concentrating BALF for IgE analysis at 40-fold. Overnight incubation maintained the same sensitization profile while increasing sensitivity. Reproducibility was demonstrated ($R^2 = 0.97$), as was specificity using protein inhibition assays. Arthropods, fungi, and pollens showed the greatest discrimination for SEA.

Conclusions and Clinical Importance: We have established that protein microarrays can be used for large-scale IgE mapping of allergens associated with the environment of horses. This technology provides a sound platform for specific diagnosis, management, and treatment of SEA.

Keywords: allergen, horse, IgE, protein microarray, severe equine asthma
1 | INTRODUCTION

Severe asthma in horses, known as severe equine asthma (SEA), is a performance-limiting, allergic response to inhaled allergens in genetically predisposed horses that affects approximately 14% of the equine population in the United Kingdom.\(^1\)\(^-\)\(^3\) Allergen exposure in affected horses results in small airway inflammation, mucus hypersecretion, and bronchoconstriction, altering pulmonary resistance, dynamic compliance, and pleural pressure.\(^4\)\(^-\)\(^6\) The predominant source of these aeroallergens is the organic dust portion of forage and bedding, which contains fungi, bacteria, pollen, and arthropods.\(^7\)\(^-\)\(^11\) Removal from the aeroallergen-rich stabling environment results in some degree of remission,\(^12\) but owner compliance is limited because of seasonality, competition schedule, health issues, and nutritional demands. Treatments with corticosteroids and bronchodilators provide short-term relief, but such therapeutic approaches have been associated with undesirable adverse effects, and their use is prohibited under Fédération Équestre Internationale and Jockey Club rules.\(^13\),\(^14\) Allergen avoidance is the cornerstone of prevention and effective treatment, but the efficacy of the latter approach relies on identification of causal allergens.\(^15\)

Currently, the main obstacles to diagnostic and therapeutic developments include major limitations in the number of allergens screened to establish causal agents and lack of a clinically applicable in vitro test.

The pathogenesis of this condition remains unclear, but several studies have implicated immunoglobulin E (IgE) by in vitro histamine release assays,\(^15\)\(^-\)\(^18\) natural hay and straw challenges,\(^19\) intradermal testing,\(^20\) and specific IgE (sIgE) analysis of bronchoalveolar lavage fluid (BALF) and sera.\(^21\),\(^22\) The sIgE assays suggest that Aspergillus fumigatus, Alternaria alternata, rAsp f 8, Thermo Scientific Pierce Mini-Protease Inhibitor Tablets–EDTA free (product # 13437766). The mixture was gently agitated and incubated at 4°C for 10 minutes before addition of 2.5 mL of glycerol (Fisher Scientific, Leicestershire, United Kingdom) and stored at −80°C until analysis. To concentrate, BALF was thawed, maintained at 4°C, and filtered using a Sartorius Stedim 0.45-μm filter syringe (product # 17598). The BALF samples then were concentrated in an Amicon Ultra-15 centrifugal filter (product # UFC905024) and used immediately. Blood was collected, and sera were prepared as previously described,\(^33\) before storage at −80°C until analysis, at which time samples were thawed at room temperature and placed on ice.

2.2 | Proteins, printing and hybridization

To maximize utility, the microarray was designed to be as comprehensive as possible by including extracts and pure proteins from a wide range of protein families derived predominately from fungi, bacteria, pollen, and arthropods. The extracts and pure proteins were obtained from commercial suppliers, produced in house, and from donations. Because of the limited commercial availability of some bacterial and fungal protein extracts, it was necessary to produce them in house. Lypophilized purified samples of the desired strain were purchased from Deutsche Sammlung von Mikroorganismen und Zellkulturen (https://www.dsmz.de) and grown in 150 mL of liquid media according to the supplier’s recommendation (250-mL Erlenmeyer flask). Once grown, the media were centrifuged in 50-mL tubes at 4000 g for 10 minutes, and the supernatant was carefully removed before washing the individual pellets in 5 mL of phosphate buffered saline (PBS). The tubes were centrifuged at 4000 g for 10 minutes, the supernatant was removed, and 1 mL of lysis buffer solution was added to each tube (PBS, 0.5% TritonX-100 wt/vol and Thermo Scientific EDTA free protease inhibitor mini-tablet). The resuspended pellets were pooled into a single 50-mL centrifuge tube, placed on ice, and sonicated using an MSE Soniprep 150 (15 seconds sonication with 30-second cooling periods in between for 10 cycles). Subsequently, the solution was filtered through a Nalgene 0.45-μm syringe filter (product # 190-25-45), and the protein content quantified using a Pierce Bicinchoninic Acid Protein Assay Kit (product # 23225). The remaining solution underwent lypophilization, was resuspended in MiliQ water with 10% glycerol (filtered through a 0.02 μm syringe filter), and was normalized to 1 mg/mL protein and stored at −80°C.
Bronchoalveolar lavage concentration work initially was conducted using slides described previously and consisting of extracts (n = 240) and pure proteins (n = 120) from a range of protein families, including fungi, pollens, and arthropods, to establish the optimal BALF concentration to be utilized in subsequent development work. In house extracts not present in the initial array setup were tested by printing normalized samples (1 mg/mL protein) onto 16-pad FAST slides (Whatman Schleicher & Schuell, Dassel, Germany) using a QArrayllte arrayer (Genetix, United Kingdom). After sample selection, a new set of 384 proteins (see Supporting Information Appendix) was printed in a professional setting using a Marathon microarrayer (ArrayJet, Roslin, Scotland) printer as previously described with an approximate spot size of 200 μm diameter and replicated with even spacing 2 times across each of the individual 16 pads into 2 identical blocks to final spot density of 12,288 spots/slide. For alignment and quality control, spots of Cy3, Cy5, and 16 pads into 2 identical blocks to final spot density of 12,288 spots/slide. For alignment and quality control, spots of Cy3, Cy5, and Cy6 were printed onto each slide. Once printed, slides were blocked for 1 hour at 37°C in 3% bovine serum albumin (BSA; wt/vol) in PBS inside a Corning 5 slide holder (product # 40082) using a mini hybridization oven (Appligene, USA), washed 3 times for 2 minutes in PBS containing 0.05% (wt/vol) Tween-20, followed by five 1-minute washes with MiliiQ water, and dried by centrifugation (MSE Mistral 3000i, Sanyo, United Kingdom) at 1000g for 10 minutes at room temperature.

Slides were fitted with Proplate slide modules (Grace Bio-Labs, product #204862) and washed 3 times (60-second dwell time) with PBS with Tween 20 (PBST; Tween at 0.2%). Samples (BALF/sera) were diluted in a ratio of 1:2 with 4% BSA in PBST (Tween at 0.4% wt/vol) containing Thermo Scientific Pierce Mini-Protease Inhibitor Tablets—EDTA free (product #13437766; 1 tablet in 5 mL), which previously had been passed through a Whatman 13-mm, 0.45-μm filter syringe (product #6784-1304). One hundred microliters of the prepared sample was added to each well, excluding well 4, which was used as control and filled with 100 μL of the dilution solution (1:2) in PBS. The Proplate was fitted with an adhesive seal strip and incubated for 16 hours at 4°C on the Stuart mini see-saw rocker (SSM4) at 12 oscillations/minute. Slides were washed 3 times with PBST (Tween at 0.05%) using the BioTek plate washer and incubated for 2 hours at 37°C in a ThermoHybaid (HyPro 20) at vibration setting 3 with 100 μL per well of mouse anti-horse IgE (BioRad, product #MCAS592GA) in a ratio of 1:400 in 1% BSA in PBST (Tween at 0.2% w/v), washed 3 more times with PBST (Tween at 0.05%) and incubated for 1 hour at 37°C in the ThermoHybaid with 100 μL per well of Dylight 649 conjugated anti-mouse IgG1 (Rockland, product #610-434-040) in a ratio of 1:400 in 1% BSA in PBST (Tween at 0.2% wt/vol). The slide then was washed 3 times in PBST (Tween at 0.05%) followed by 3 washes with Milli-Q water, and dried by centrifugation at 300×g for 10 minutes (Mistral 3000i, rotor 43124-708).

Data analysis

Processed slides were scanned in a GenePix 4000B (Molecular devices, USA) with the photomultiplier tube settings at 440 and 310 at 635 and 532 nm, respectively, and saved as TIF files. Images were processed in GenePix Pro software v6.0.1.27 (Axon Instruments) and saved as comma-delimited text files. Fluorescence values were calculated for each spot by subtracting local background from the median fluorescence value of the spot. One pad per slide contained all reagents with addition of PBS instead of serum for control purposes; these results were deducted from samples on the same slide to account for any protein autofluorescence and nonspecific binding. Further analysis and data presentation were carried out using Microsoft Excel. Average fluorescence values for each protein were compared between SEA and control groups using a conventional Z-test in Excel (Microsoft, USA). The Benjamini-Hochberg method was used to account for false discovery at a rate of 0.05. Benjamini-Hochberg corrected values were considered significant at P < .05. Linear regression (coefficient of determination) of IgE fluorescence values for all proteins (n = 384) was used to establish the relationship between BALF and sera, reproducibility of results, and various mouse anti-horse IgE sources. Bronchoalveolar lavage fluid concentration techniques and concentrations were tested by 1-way analysis of variance. Tukey's honestly significant difference test for multiple comparisons was performed if significant differences were found (P < .05).

3 | RESULTS

3.1 | Optimizing sera incubation conditions

3.1.1 | BALF concentration techniques

Bronchoalveolar lavage fluid concentration employing Amicon and PD10/lyophilizing methods were compared using a BALF pool from 6 horses (n = 3 SEA and 3 control). Total IgE for each protein group was used to compare concentration methods (Figure 1A) and indicated no significant difference (P > .05) between concentration techniques. The Amicon concentration method was used to evaluate optimal BALF concentration by total IgE fluorescence for each protein group, indicating that a plateau was reached at 40-fold concentration (Figure 1B). Therefore, all subsequent BALF concentrations were carried out by Amicon filtration to a 40-fold final concentration.

3.1.2 | Incubation time

Two conditions were tested for optimal sera incubation times using a sera pool from 6 horses (n = 3 SEA and 3 control): 3 hours at 37°C as previously used for equine sera and overnight (16 hours) at 4°C, which previously has been shown to be more sensitive in studies performed in humans. As shown in Figure 2, the IgE profile between the 2 incubation times was significantly correlated (R² = 0.76). However, when the serum was incubated for 16 hours at 4°C, it was more sensitive with 28.1% of proteins showing positive reactions, compared to the 3 hours incubation, which showed 16.4% of proteins with positive reactions (data not shown). Therefore, subsequent serological incubations were conducted overnight at 4°C to increase sensitivity.

3.1.3 | Comparison of specific IgE in BALF and sera

Bronchoalveolar lavage samples concentrated by Amicon (40-fold) were compared with sera from 6 horses (n = 3 SEA; n = 3 control),
and correlation coefficients were calculated for each separate protein group. Strong correlations were found between BALF and sera (Table 1). Thus, all subsequent incubations were conducted with serum because it is far easier to obtain, less invasive, more economical, and stable to transport. Horse 5, a clinically healthy horse, showed poor BALF/sera correlations across all protein groups, which was thought to be a result of the horse recently changing to a different barn on the same yard and, therefore, localized IgE production in the lung because of environmental allergen correlated poorly with serological IgE.23,35

3.2 | Reproducibility

3.2.1 | Printing lot variation

The effect of printing lot on reproducibility of the protein microarray was assessed using 2 microarray slides printed on the same day. Sera from 3 SEA and 3 control horses was hybridized on the 2 slides simultaneously. Fluorescence results from replicate arrays were evaluated using linear regression and indicated that fluorescence results from the array were repeatable between printing lots ($R^2 = 0.97$).
3.2.2 | Comparison between monoclonal mouse anti-horse 3H10 sources

Two mouse anti-horse IgE monoclonal antibodies (derived from the 3H10 clone) were compared using linear regression of the fluorescence results using a sera pool from 6 horses (n = 3 severe equine asthma; n = 3 control) using two mouse anti-horse IgE 3H10 clones; Wilson et al.,36 and BioRad (product # MCA5982GA).

As shown in Figure 3, the fluorescence results from the array had a correlation coefficient of $R^2 = 0.91$, indicating a significantly similar IgE profiles.

3.3 | Specificity—protein inhibition assay

To test the IgE specificity of IgE-protein binding, a protein inhibition assay was performed to assess cross-reactivity, in which pooled sera were spiked with several proteins in serial dilution and the effect on related and neighboring proteins evaluated. A protein inhibition assay enables the confirmation of specificity of an antibody against the target protein and usually is conducted using several proteins to confirm both the antibody’s specificity to the target protein and to assess potential cross-reactivity.34 Two different protein inhibition groups were used, each containing 2 different proteins. Group 1 consisted of Blattella germanica (Bla g 1) and Rumex crispus (Rum cr), and group 2 consisted of Penicillium notatum (Pen ch) and Acinetobacter gerneri (Aci g). Interestingly, decreased fluorescence from proteins other than those targeted also was observed, indicating either nonspecific inhibition or some similarity among the allergenic components of the proteins. Group 1 showed no nonspecific binding in the bacteria, arthropod, or fungi groups, but cross-reactivity was seen among grass pollens, most notably Cynodon dactylon, Rc r i s p u s, Zea mays, and Anthoxanthum odoratum.

Group 2 demonstrated no nonspecific binding in the bacteria, arthropod, and pollen groups, but cross-reactivity was seen among Aspergillus niger, Aspergillus versicolor, Penicillium expansum, P notatum, Aspergillus nidulans, and A fumigatus (Figure 4).

3.4 | Allergen comparison

Whether or not the prototype array was able to identify novel allergens associated with SEA was assessed using Z-tests with Benjamini-Hochberg adjusted $P$-values among 6 SEA and 6 control sera samples. The results shown in Table 2 confirmed the ability to conduct IgE
profiling and identify potential SEA allergens using microarray methods. As expected, it confirmed the presence of fungi and mite as main reactants in the SEA population, while also identifying an association with pollen which has not been implicated previously."

4 | DISCUSSION

We previously have determined the sensitivity and specificity of microarrays in the diagnosis of insect bite hypersensitivity, confirming the high discriminatory power of complex extracts and pure recombinant *Culicoides* proteins associated with the allergy. Based on these principles, an array was constructed to enable multiallergen testing and assess the complex sensitization of profiles associated with SEA in a single assay, based on proteins in the environment of the horse. The use of protein extracts was essential because very few proteins have been assessed in relation to SEA to date. Therefore, in the early stages of development, we used a range of extracts to maximize coverage in combination with pure proteins, where available or where the allergen has been previously associated, thus simultaneously maintaining specificity. Furthermore, we observed comparable accuracy between natural extracts and recombinant allergens, whereas some studies have indicated that the use of the recombinant component alone may be insufficient for some allergens. Although the eventual goal will be to move toward component-resolved diagnostics utilizing individual allergen molecules for increased sensitivity and minimizing cross-reactivity, the genus and species must be identified to enable the production of pure proteins. Component-resolved diagnostics offers markedly increased accuracy over routine diagnostic tests (eg, skin prick and specific IgE determination), and enables the accurate selection of allergens to be used for allergen immunotherapy. Moreover, the identification of sensitization to pure proteins will assist in development of diagnostic tests and treatments. This microarray approach has several advantages. It allows substantial allergen profiling with minimal sample, collection of less invasive readily obtained in vivo samples, permits automation, and enables the generation of mathematical predictive models to assist in clinical allergy diagnosis.

Protein microarray methods primarily consist of 2 steps: first, the printing of proteins onto the nitrocellulose slides, and second, the profiling of equine IgE. Printing methods are well established; therefore, the latter was optimized to enable analysis of SEA BALF and sera samples. Although it has been suggested that developing technology means sensitivity is such that many immunoglobulin isotypes in BALF can be assessed unconcatenated to the nanogram or microgram, it is often not possible to detect allergen-specific IgE in BALF because of the low concentration of the isotype present. Therefore, concentration techniques often must be employed to assess BALF IgE. Lyophilization and centrifugal filtration methods have been successfully utilized to concentrate BALF for immunoglobulin analysis, but certain techniques, such as ammonium sulfate precipitation, can result in denaturation of the liable epitopes. Similarly, lyophilizing BALF samples without desalting results in high concentrations of sodium chloride, which can denature proteins. The most commonly utilized BALF concentration technique is the centrifugal filter (Amicon Ultra-15 or Centricon-10) to a 10-fold concentration of immunoglobulin, but even this technique results in a 20% loss of specific IgE and IgG.

On collection of BALF for immunoglobulin analysis, protease inhibitors must be added to prevent proteolytic cleavage of proteins, which would otherwise leave the immunoglobulin unviable. Similarly, immunoglobulin in BALF is markedly affected by freeze–thaw cycles, and the inclusion of a cryopreservative in the form of glycerol has been shown to be effective. Therefore, glycerol was added as a cryoprotectant to a final concentration of 20% to help stabilize the proteins and prevent formation of ice crystals during freezing that destroy protein structure. Unfortunately, samples containing cryopreservative tend to thaw during lyophilization, meaning it was not possible to achieve a 40-fold concentration using this technique. To avoid this problem and remove sodium chloride, samples underwent a buffer exchange using a PD-10 column before lyophilization. Bronchoalveolar lavage concentrations and techniques were trialed, varying hybridization temperatures and times were assessed, and BALF/sera analyzed. The highest binding capacity was observed with overnight incubation at 4°C. When using BALF, the highest binding was seen using the Amicon filter and the PD-10 elution column/lyophilizing at a 40-fold final concentration. The Amicon filter technique was quicker, easier, decreased the risk of contamination,
and had previously been utilized, and, therefore, this technique was selected. Interestingly, during optimization, a biased response toward pollens was observed. Plants are polyploids and show a large number of gene duplications; hence, high cross-reactivity among species generally is observed. It is our experience that pollen response in humans and other animals is commonly amplified.51

Because of the significant correlation of BALF and sera (average $R^2 = 0.75$), sera were used in subsequent analysis because of the ease of use. Previous studies comparing the specific IgE profiles of BALF and sera using ELISA techniques have been limited and contradictory to date. Previous authors concluded that although BALF may be valuable for analysis, sera was of little clinical relevance.21,23 Here, we demonstrated the ability to profile unconcentrated sera instead of BALF to assess potential allergens. This approach has several advantages because serum is far easier to collect, store, and prepare for analysis in comparison to BALF. Collection also is less stressful for the horse. Moreover, it holds further potential in the use of diagnostic microarrays because serum is far more stable to ship for analysis.52

Repeatability is an essential factor in the development of new diagnostic tests. Therefore, the effects of printing lot and mouse anti-horse IgE 3H10 sources were assessed. These results confirmed reproducibility among printing lots (average $R^2 = 0.97$). The original mouse anti-horse IgE 3H10 used was that from a previous study.40 The commercial availability of antibodies is essential in diagnostic tests; therefore, the 3H10 clone40 was compared with the commercially available BioRad 3H10 (product # MCA5982GA), confirming reproducibility with the commercially available clone ($R^2 = 0.90$).

Specificity is an important aspect of protein microarrays, which was confirmed by a protein inhibition assay. In this assay, some cross-reactivity was seen, predominantly with grass pollens, as well as with Aspergillus and Penicillium. A previous study reported that pollens from grasses (Poaceae) often had high immunological cross-reactivity, potentially indicating common antigenic/allergenic component(s).53 Furthermore, cross-reactivity was identified between the genus Penicillium and Aspergillus, which is expected because taxonomically, the genera Penicillium and Aspergillus have many similarities, because both produce and contain galactomannans with similar galactofuranosyl and immunogenic side chains. Cross-reactivity in the fungi group was seen only with whole protein extracts, emphasizing the importance of including pure proteins. Analysis of human sera in a variety of assays has indicated that A. fumigatus contains determinants in common with Cladosporium, Candida, Alternaria, Trichophyton, and Epidermophyton,54 but cross-reactivity was not identified here.

Several allergens of interest identified in our study were consistent with those previously identified as SEA-associated by ELISA, Western blot, and RAST methods (A. fumigatus, A. alternate, E. amstelodami, and G. candidum). Ours was the largest panel of proteins tested with a controlled SEA group to date and thus identified new and relevant allergens. Several SEA-associated allergens identified in our study previously have been associated with allergic asthma in humans (eg, Dermatophagoides farina, B. germanica, Aspergillus restrictus, Dermatophagoides pteronyssinus). The novel SEA-associated allergens identified in our study strongly implicate fungi and mite as the main reactants, as well as identifying previously unrecognized reaction with pollens. This observation confirms the future potential of specific IgE as a biomarker for the serological diagnosis of SEA.

Our results have established a reliable protein microarray for large-scale IgE profiling of environmental proteins of horses, confirming identified SEA-associated allergens and elucidating a range of previously unidentified allergens. The technique is sufficiently sensitive and specific to differentiate between sensitized allergens in SEA and in control horses. Furthermore, the developed serological assay enables accurate identification of an individual horse’s sensitization profile. This information provides a reliable, fast, and repeatable method for screening a wide variety of potential allergens found in the stable environment in a miniaturized and affordable format, while offering a platform to support management and treatment of this debilitating respiratory disorder in horses.
