### ABSTRACT

Heterogenous photocatalysts based on electrospun fibers composed of polyvinylpyrrolidone and titanium propoxide were prepared and heated at 500, 750 and 950 °C to obtain anatase and rutile fibers. The fibers were then decorated with Pd and Co nanoparticles as well as a symmetrical zinc phthalocyanine (Pc). The fibrous materials obtained have a paper-like macroscopic appearance allowing for easy handling and separation. The photocatalytic activities of the new materials were evaluated for the generation of H<sub>2</sub> upon UV (368 nm) or visible (630 nm) light excitation. Depending on the heat treatment or the post-synthetic decoration method, the materials show higher, or similar, activity compared to P25-TiO<sub>2</sub>, with superior ease of separation. The catalysts showed ability to degrade organic matter, with MeOH used as a model compound. This is of considerable importance for potential water treatment applications that will require flow-compatible materials.

### 1. Introduction

Increased water pollution and the need for a cleaner environment have resulted in increased interest in heterogenous photocatalysis [1]. According to a 2017 report from the World Health Organization (WHO), over 2 billion people do not have access to safe water in their homes [2]. The degradation of water pollutants while simultaneously producing H<sub>2</sub> is an area of interest, mainly because H<sub>2</sub> has been identified as potential candidate in energy production, for example by powering fuel cells [3]. Solar water splitting to produce H<sub>2</sub> mediated by catalysts such as TiO<sub>2</sub> has risen interest since the 1972 landmark report by Fuhishima and Honda [4]. TiO<sub>2</sub> is particularly attractive because it has a high resistance to corrosion, possesses strong oxidising ability and it is a low-cost material [5–7]. Typical titania catalysts, including many materials described as fibers or wires at the microscopic scale, are macroscopically powders. However, for practical applications in flow systems, the separation of fine-powdered TiO<sub>2</sub> is difficult, making retrieval and reusability challenging. Hence, the TiO<sub>2</sub> fibers utilized in this work could greatly facilitate scale-up by enabling the use of flow photochemistry techniques. The TiO<sub>2</sub>-based fibers are obtained by electrospinning followed by thermal treatment, and are easy to separate from solution. Electrospinning is a commonly used fiber fabrication technique for the production of small diameter fibers with high surface-

to-volume ratio [8,9]. The TiO<sub>2</sub>-based fibers can be prepared in different crystalline phases, i.e., anatase and rutile, enabling for comparison of their activities [10–12]. Furthermore, the fibers utilised here (in spite of their nanometric diameter) have a macroscopic thin-paper-like appearance –which remains intact even post modification– that enormously facilitates their separation and/or future potential in flow system applications (Fig. 1).

True water splitting entails breaking down water to form hydrogen and oxygen in the presence of a catalyst, such as TiO<sub>2</sub> (Scheme 1A). Unfortunately, this process is rather inefficient [13,14]. Sacrificial electron donors (SEDs) are commonly used to assist the H<sub>2</sub> generation thereby improving the efficiency of H<sub>2</sub> generation at the expense of the consumption of SEDs (Scheme 1B). A range of SEDs have been reported to be effective for this process [14,15], in this work 1% methanol is used as a SED. Upon exposure to UVA irradiation, an electron-hole pair is formed in the TiO<sub>2</sub> and methanol can quench the electrophilic hole producing <sup>•</sup>CH<sub>2</sub>OH radicals (Scheme 1B), subsequently forming formaldehyde (CH<sub>2</sub>O) [16]. This process enhances the H<sub>2</sub> generation of TiO<sub>2</sub> by close to two orders of magnitude [14]. This phenomenon therefore suggests that other electron donor compounds, such as common organic water pollutants, can fulfil the role of being a SED and aid in effective generation of H<sub>2</sub> while simultaneously being degraded in the process, resulting in improved water quality [14,17].

Scheme 1. (A) True water splitting versus (B) SED assisted hydrogen generation.

The generation of hydrogen as utilized here serves as an excellent way to test for new catalyst activity, as under anaerobic conditions H<sub>2</sub> generation is directly linked to the degradation of organic matter [17]. This work explores the use of bare, phthalocyanine (Pc) decorated and metal nanoparticle (MNP) decorated TiO<sub>2</sub> fibers for H<sub>2</sub> generation using 1% methanol as a model SED. Palladium and cobalt NPs were chosen as their efficiency in hydrogen generation when used together with commercially available P25-TiO<sub>2</sub> has been established before [14]. In order to compare the activities and selectivities of the TiO<sub>2</sub>-based catalysts, their photocatalysis was conducted under 368 and 630 nm LED irradiation. The rationale behind the choices in the light sources is based on the fact that all the catalysts have TiO<sub>2</sub> as a dominant absorber in the UV region, and that the decoration of the fibers can change the optical properties of the materials, i.e., post-synthetic decoration provides visible light absorption properties to the material. Thus, decoration of the TiO<sub>2</sub> fibers with Pcs yields TiO<sub>2</sub> fibers with two absorbers wherein the Pc absorbs visible light. This is beneficial as most of the solar irradiation is in the visible region, making such work feasible for real life applications.

Pcs are synthetic tetrapyrrolic macrocycles containing four iminoindoline rings, they possess excellent visible/near infrared absorption, high thermal and chemical stability, and the ability of generate singlet oxygen [18,19]. These properties make them good candidates for applications such as dye sensitised solar cells (DSSCs), photodynamic therapy (PDT) of cancer, and photodynamic antimicrobial chemotherapy (PACT) of bacteria [20–23]. In addition, phthalocyanines have been shown to generate H<sub>2</sub>, when adsorbed on semiconductor photocatalysts such as TiO<sub>2</sub>, although not showing the ease of separation and flow-compatibility of the materials reported here [15,24]. In this work a symmetrical zinc Pc (complex 1, Fig. S1) is deposited on TiO<sub>2</sub> fibers to adapt the materials for H<sub>2</sub> generation and potential water treatment under flow conditions. Complex 1 was chosen

because it is insoluble in water, preventing further pollution of the treated water through potential leaching mechanisms.

## 2. Experimental

### 2.1. Materials

Polyvinylpyrrolidone (PVP, MW 1,300,000), titanium(IV) propoxide (TP), 1,3-diphenylisobenzofuran (DPBF), zinc acetate (Zn(OAc)<sub>2</sub>), cobalt nitrate hexahydrate, Zn phthalocyanine (ZnPc) were purchased from Sigma-Aldrich. Glacial acetic acid (AA) was purchased from Minema chemicals. Palladium (II) chloride (99%) was purchased from Alfa Aesar. Irgacure-907 (2-methyl-4'-(methylthio)-2-morpholinopropiophenone) was a gift from Ciba Specialty Chemicals. The solvents were obtained from commercial suppliers and used as received. The synthesis of complex 1 has been reported before [25,26]. Employed equipment and instrumentation are presented in the supporting information.

### 2.2. Electrospinning method

Sample preparation and electrospinning were conducted as reported before [27–30] with slight modifications. A solution of glacial acetic acid (5 mL) and titanium(IV) propoxide (5 mL) was prepared and added to a solution of 10 % PVP (10 mL) in ethanol. The resulting solution was stirred for 24 h and then loaded into a syringe equipped with a stainless steel needle, connected to a high voltage power supply. A voltage of 12.5 kV was applied between the needle and the stationary aluminium foil collector. The distance between the tip of the needle and the collector (TCD) was 12 cm and the applied flow rate was 1.5 mL/h (controlled using a syringe pump). The recorded temperature and humidity in the room in which the electrospinning was conducted were 24.7 °C

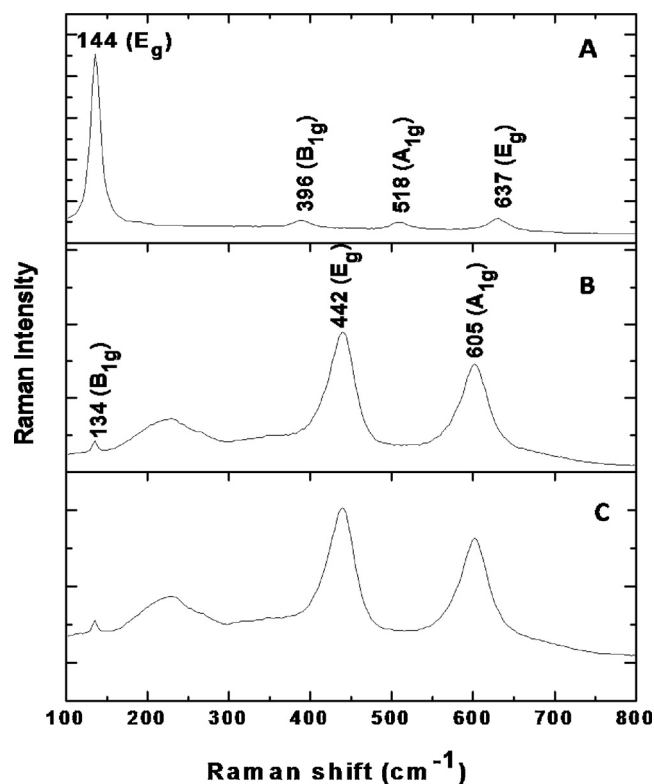

Fig. 2. Raman spectra of (A) TiO<sub>2</sub>-500, (B) TiO<sub>2</sub>-750 and (C) TiO<sub>2</sub>-950 showing characteristic bands for anatase (A) and rutile (B and C).

and 49%, respectively. The collected fiber mat was left in open air to allow for complete hydrolysis of the titanium propoxide by moisture in the air [28]. The electrospun PVP/TP composite nanofibers were calcined at temperatures of 500, 750 and 950 °C for 3 h under air, removing PVP which acts as a sacrificial polymer to obtain purely inorganic TiO<sub>2</sub> nanofibers (labelled as TiO<sub>2</sub>-500, TiO<sub>2</sub>-750 and TiO<sub>2</sub>-950, respectively).

### 2.3. Decoration of TiO<sub>2</sub> fibers

#### 2.3.1. Phthalocyanine-decorated fibers

The deposition of complex 1 on the surfaces of each of the calcined TiO<sub>2</sub> fibers (TiO<sub>2</sub>-500, TiO<sub>2</sub>-750 and TiO<sub>2</sub>-950) and on commercially available P25-TiO<sub>2</sub> (used as reference) was conducted. Complex 1 (10 mg) was dissolved in 15 mL tetrahydrofuran (THF) in four separate reaction vessels followed by immersion of TiO<sub>2</sub>-500, TiO<sub>2</sub>-750, TiO<sub>2</sub>-950 or P25-TiO<sub>2</sub> (50 mg) into each Pc solution. The solutions were then sealed and left in the dark for 24 h at room temperature. The fibers were then removed from the solutions, rinsed with THF and oven dried at 70 °C for an hour to remove the THF. The TiO<sub>2</sub> based catalysts obtained were blue and are labeled TiO<sub>2</sub>-500-1, TiO<sub>2</sub>-750-1, TiO<sub>2</sub>-950-1 and P25-TiO<sub>2</sub>-1.

#### 2.3.2. Pd-decorated fibers

PdNPs were synthesized by reduction of Pd<sup>2+</sup> under UVA irradiation in the presence of the calcined TiO<sub>2</sub> fibers (TiO<sub>2</sub>-500, TiO<sub>2</sub>-750 or TiO<sub>2</sub>-950) or P25-TiO<sub>2</sub>. This was done following the protocols previously described [31] with slight modifications. Each of the calcined fibers and P25-TiO<sub>2</sub> (500 mg) together with PdCl<sub>2</sub> (22 mg) were added to 20 mL water in separate reaction vessels followed by UVA irradiation in a photoreactor for 8 h. The fibers were then rinsed with water and dried overnight in a desiccator. Brown Pd decorated TiO<sub>2</sub> based catalysts were obtained and denoted TiO<sub>2</sub>-500-Pd, TiO<sub>2</sub>-750-Pd, TiO<sub>2</sub>-950-Pd and P25-TiO<sub>2</sub>-Pd.

#### 2.3.3. Co-decorated fibers

The Co-decorated TiO<sub>2</sub> catalysts were also obtained following the protocols previously described [32] with slight modifications. Irgacure-907 (I-907) was used as a photoinitiator for the photochemical reduction of Co<sup>2+</sup> to CoNPs. Each of the calcined fibers and P25-TiO<sub>2</sub> (160 mg) were added to a 20 mL solution of 1 mM cobalt nitrate and 2 mM I-907 in argon-saturated acetonitrile, followed by irradiation in a photoreactor for 2 h. The fibers were then rinsed with water and left to dry overnight. Due to the instability of the CoNPs in the presence of oxygen, the otherwise black and paramagnetic CoNPs do not exhibit paramagnetic behaviour in the presence of air and resulted in grey/white Co decorated TiO<sub>2</sub> based catalysts which were denoted TiO<sub>2</sub>-500-Co, TiO<sub>2</sub>-750-Co, TiO<sub>2</sub>-950-Co and P25-TiO<sub>2</sub>-Co, respectively.

#### 2.4. Photo-induced hydrogen generation

Each of the functionalised fibers (10 mg) were suspended in 4 mL of 1% methanol aqueous solution under argon atmosphere and sealed in a crimp top vial followed by irradiation for 4 h. For comparison, the photoactivity of commercially available P25-TiO<sub>2</sub> was studied under the same conditions. Samples of the headspace gas were then taken with a sample lock syringe and injected in the GC-TCD wherein the H<sub>2</sub> signal was detected at ~ 4.0 min. The quantification of H<sub>2</sub> was performed using the already reported calibration curve of the gas detection in the GC-TCD instrument in the group [14].

## 3. Results and discussion

### 3.1. Characterization of TiO<sub>2</sub> fibers

The titania fibers were characterised using Raman, XPS, and DR spectroscopies, XRD and TEM. The Raman spectra are shown in Fig. 2. TiO<sub>2</sub>-500 was found to have active vibrations in Raman spectroscopy located at 144 cm<sup>-1</sup> (E<sub>g</sub>), 396 cm<sup>-1</sup> (B<sub>1g</sub>), 518 cm<sup>-1</sup> (A<sub>1g</sub>) and 637 cm<sup>-1</sup> (E<sub>g</sub>) while for TiO<sub>2</sub>-750 and TiO<sub>2</sub>-950, vibrations at 134 cm<sup>-1</sup> (B<sub>1g</sub>), 236 cm<sup>-1</sup> (broad band), 442 cm<sup>-1</sup> (E<sub>g</sub>), and 605 cm<sup>-1</sup> (A<sub>1g</sub>) were observed, corresponding to reported vibrations for anatase and rutile crystalline phases of TiO<sub>2</sub> [33]. The results suggest that TiO<sub>2</sub>-500 is pure anatase while TiO<sub>2</sub>-750 and TiO<sub>2</sub>-950 are pure rutile.

XRD analyses were also conducted to confirm the crystalline structure of the TiO<sub>2</sub> fibers. XRD patterns of the calcined fibers are shown in Fig. 3 where strong diffraction lines are observed, each of which showing high crystallinity and single phases of the TiO<sub>2</sub> fibers. The peak positions of TiO<sub>2</sub>-750 and TiO<sub>2</sub>-950 are the same suggesting

Fig. 3. XRD patterns of (A) TiO<sub>2</sub>-500, (B) TiO<sub>2</sub>-750 and (C) TiO<sub>2</sub>-950; A = anatase and R = rutile.

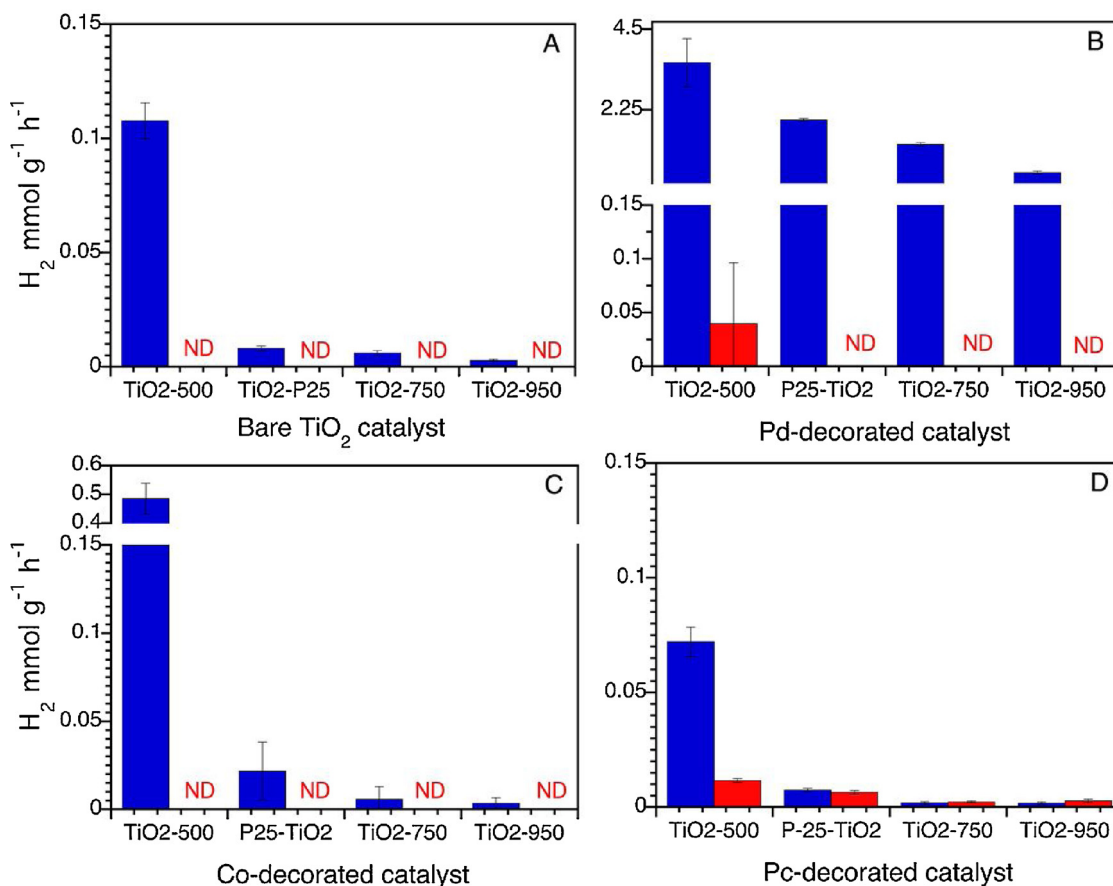

**Fig. 4.** SEM images of (i)  $\text{TiO}_2$ -500, (ii)  $\text{TiO}_2$ -500-Pd, (iii)  $\text{TiO}_2$ -500-Co, (iv)  $\text{TiO}_2$ -750, (v)  $\text{TiO}_2$ -750-Pd (vi)  $\text{TiO}_2$ -750-Co, (vii)  $\text{TiO}_2$ -950 (viii)  $\text{TiO}_2$ -950-Pd (ix)  $\text{TiO}_2$ -950-Co. The size bar (bottom center of each image) is 1  $\mu\text{m}$ .

that they have the same phase while those of  $\text{TiO}_2$ -500 are different. For  $\text{TiO}_2$ -500, peaks were observed at the  $2\theta$  values of 25.37, 37.89, 48.02, 54.07, and 55.20 corresponding to the (101), (004), (200), (105) and (211) planes of tetragonal anatase phase as reported before [8]. For  $\text{TiO}_2$ -750 and  $\text{TiO}_2$ -950 on the other hand, the main peaks were observed at  $2\theta$  values of 27.90, 36.63, 41.83, 54.63 and 57.03° corresponding to the (110), (101), (111), (211) and (220) planes of tetragonal rutile phase as reported before [8].

The MNP- and Pc-decorated fibers were characterized by UV-vis spectroscopy. The spectrum of complex **1** in THF is shown in Fig. S2 where the two major absorption bands associated with Pcs, i.e., the Q band (accompanied by two vibronic bands) in the near infrared region ( $\sim 680$  nm) and a weaker B band towards the ultraviolet region were observed. The narrow Q band of the Pc at 680 nm served as confirmation of its monomeric behaviour in THF. Solid state spectroscopy of the fibers was also conducted as shown in Fig. S3 (using  $\text{TiO}_2$ -500,  $\text{TiO}_2$ -500-1,  $\text{TiO}_2$ -500-Pd and  $\text{TiO}_2$ -500-Co as examples). The diffuse

reflectance spectra of the calcined  $\text{TiO}_2$  fibers show a broad peak in the UV region ( $< 400$ ) which is characteristic for  $\text{TiO}_2$  materials [34]. The peak attributed to  $\text{TiO}_2$  was maintained after deposition of the Pd and Co NPs as well as complex **1** on the surface of the  $\text{TiO}_2$  fibers. The fibers decorated with the PdNPs exhibit a slight red shift and broadening in the spectral band which is not observed for the fibers decorated with the Co nanoparticles. In addition, there is also an observed red shift of the Pc Q band (692 nm) for the fibers decorated with complex **1**. The red shift and broadening of the Q band are typical of Pcs in the solid state, mainly due to aggregation, which is judged by broadening and splitting of the Pc Q band [35,36]. The inset in Fig. S3 shows the macroscopic appearance of the materials, clearly fibers retain their paper-like fibrous morphology upon the post-synthetic decoration and change from white to gray or green color accordingly. Similar spectra were obtained for  $\text{TiO}_2$ -750 and  $\text{TiO}_2$ -950 as well as their decorated counterparts.

Analysis of the metal loading on each of the calcined fibers was

**Fig. 5.** H<sub>2</sub> generation rates with (A) bare fibers, (B) fibers decorated with Pd NPs, (C) fibers decorated with Co NPs and (D) fibers decorated with complex 1. Tests were conducted using an irradiance of 16 W m<sup>-2</sup> at 368 nm (blue) and 630 nm (red) in the presence of 1% methanol. ND: not detected.

conducted using ICP-OES and the results obtained are shown in Table S1. It is important to note that the Pd loadings on the three fibers (TiO<sub>2</sub>-500-Pd > TiO<sub>2</sub>-750-Pd ~ TiO<sub>2</sub>-950-Pd) are different. This is related to the preparation method of the Pd-decorated fibers. This method uses the reducing properties of TiO<sub>2</sub> to reduce Pd<sup>2+</sup> into Pd<sup>0</sup>, thus the fibers catalyse the photoreduction process. TiO<sub>2</sub>-500-Pd has a greater Pd loading (~3.26 wt %), presumably as a result of a higher photoreduction efficiency of TiO<sub>2</sub>-500, while TiO<sub>2</sub>-750-Pd and TiO<sub>2</sub>-950-Pd have comparable loadings (~1.3 wt %). This is not surprising as the pore volume (BET, see below) of TiO<sub>2</sub>-500 is larger (0.167 cm<sup>3</sup>/g) than that of TiO<sub>2</sub>-750 (0.013 cm<sup>3</sup>/g) and increased porosity has been reported to increase the catalytic activity [15]. In addition, anatase phase TiO<sub>2</sub> has been reported to possess better photocatalytic activity than rutile [24]. In the case of Co decoration, same loadings are found, as I-907 was used as reducing agent. In the case of the Pc decorated fibers, no activity of the fibers is used for derivatization, they are dyed in the same manner hence the loading is also the same. Notice that the loading for the Pc-decorated fibers was determined based on the presence of Zn (central metal of the Pc).

Confirmation of efficient photoreduction of Pd<sup>2+</sup> and Co<sup>2+</sup> to form the nanoparticles on the surface of the bare fibers was conducted by XPS using TiO<sub>2</sub>-500-Pd and TiO<sub>2</sub>-500-Co as examples. A Pd 3d core level spectrum consisting of two components i.e., Pd 3d<sub>5/2</sub> and Pd 3d<sub>3/2</sub> (separated by approximately 5.4 eV) was obtained as reported before [37]. As shown in Fig. S4A, the Pd 3d spectrum of TiO<sub>2</sub>-500-Pd was deconvoluted to four peaks at 336.9 (Pd<sup>0</sup>), 337.7 (Pd<sup>2+</sup>), 342.3 (Pd<sup>0</sup>) and 343.9 eV (Pd<sup>2+</sup>). The Pd<sup>0</sup> peaks are of higher intensity than those of Pd<sup>2+</sup> which could be an indication that although there are still traces of Pd<sup>2+</sup> in the fibers, the nanoparticles in the form of Pd<sup>0</sup> are dominant. For the CoNPs, the Co 2p core level spectrum was performed by using

two spin-orbit split components i.e., Co 2p<sub>3/2</sub> and Co 2p<sub>1/2</sub> (separated by 15.5 eV) as observed before [38]. As shown in Fig. S4B, the Co 2p spectrum of TiO<sub>2</sub>-500-Co was deconvoluted to two peaks at 778.1 (Co<sup>0</sup>) and 793.6 eV (Co<sup>0</sup>). To our surprise, given the easy oxidation of Co, the results support the complete reduction of Co<sup>2+</sup> to Co<sup>0</sup>.

Analyses of the topography of the calcined fibers before and after deposition of the MNPs were conducted using SEM (Fig. 4). Some of the calcined fibers are visibly porous; this is a good attribute relative to the commercially available P25-TiO<sub>2</sub> (image not shown) as it has been reported that porous nanostructured materials are more efficient photocatalyst [15]. This is due to their better mass transport, large specific surface area and abundant active sites for the reactions [39]. TiO<sub>2</sub>-750 and TiO<sub>2</sub>-950 have both been proven to be rutile (XRD and Raman spectra), they however possess different morphologies. The TiO<sub>2</sub>-750 fibers are more cylindrical and porous while TiO<sub>2</sub>-950 has a more distorted surface with grain-like structures which are sintered. The distortion of the fibers with increased calcination temperature is possibly due to the breakage of the Ti-O bonds in the anatase structure, permitting the rearrangement of Ti-O to form the thermodynamically stable rutile phase. Thus, phase transformation can lead to the disruption of the lattice of TiO<sub>2</sub> [40]. There are no notable differences in the images of fibers decorated with complex 1 because of the small sizes of the Pcs (about 1 nm) hence their images are not shown. The decoration of the fibers with the Pd and Co NPs on the other hand is visible on the images as the surfaces of the fibers appear rough due to the presence of the NPs.

Since some of the fibers are visibly porous (Fig. 4), the analyses of their surface areas and porosity was conducted, Table S1. No BET isotherm and hence no surface area/porosity data was obtained upon analysis of the bare and decorated TiO<sub>2</sub>-950 fibers, this is probably due

**Scheme 2.** Mechanism of photoactivity of the decorated TiO<sub>2</sub> fibers under UVA (A) and visible (B) irradiation and in the presence of methanol as SED. Note that the  $\cdot\text{CH}_2\text{OH}$  radical can donate an electron to the CB and contribute to hydrogen generation.

to their brittle nature and distorted fibers. Analyses of the bare TiO<sub>2</sub>-500 and TiO<sub>2</sub>-750 fibers shows that increased heating temperature caused a decrease in the surface area and pore volume of the fibers. Decoration of the bare fibers with NPs resulted in an increased surface area for TiO<sub>2</sub>-500-Pd (or Co) and TiO<sub>2</sub>-750-Pd (or Co), the former being larger than the latter. Decoration of the fibers with complex **1** only slightly affected the fibers surface area and porosity, attributed to the small size and low loadings of **1**. A significant decrease in pore volume and increase in surface area was also observed for TiO<sub>2</sub>-500-Pd and TiO<sub>2</sub>-750-Pd, possibly because the PdNPs fill and clog the fiber pores with that pattern not being observed for the Co decorated fibers.

### 3.2. Photo-induced hydrogen generation

The generation of H<sub>2</sub> was evaluated for each of the functionalized fibers and, for comparison, P25-TiO<sub>2</sub> in the presence of 1% of methanol. H<sub>2</sub> generation from the bare fibers (Fig. 5A) showed that the pure anatase fibers (TiO<sub>2</sub>-500) have better photoactivity compared to rutile counterparts, as previously suggested [40]. The high activity of anatase relative to rutile has also been ascribed to it having slower charge recombination kinetics than rutile [41,42]. Indeed, P25-TiO<sub>2</sub> (comprised by > 70% anatase and small amounts of rutile and amorphous phase [43,44]) shows poorer activity comparing to TiO<sub>2</sub>-500, but better activity than TiO<sub>2</sub>-750 and TiO<sub>2</sub>-950 (pure rutile). The bare fibers showed no activity at 630 nm, which was expected as TiO<sub>2</sub> does not absorb visible light [45]. The use of selected LED wavelengths (368 and 630 nm) facilitates the distinction of effects resulting from TiO<sub>2</sub> excitation and those due to excitation of decorating materials.

Using Co-decorated fibers under UV light excitation (Fig. 5C), the H<sub>2</sub> generation was enhanced ~5 times comparing to the bare fibers, similar to our observations with powder nanometric TiO<sub>2</sub>. More interestingly, Pd-decorated fibers showed a 35-fold increase in activity (Fig. 5B). This correlates to what has been observed before where PdNPs were found to be good at enhancing SED assisted H<sub>2</sub> generation while CoNPs enhance true water splitting (in the absence of a SED) [14]. Decoration of the fibers with complex **1** showed a decrease in H<sub>2</sub> generation using UV excitation. Thus, although a zinc Pc has been reported to be effective in H<sub>2</sub> generation [15], our results showed lower H<sub>2</sub> generation for catalysts decorated with complex **1** relative to the bare TiO<sub>2</sub> fibers under UV irradiation. However, under visible light irradiation the Pc-decorated fibers with the best reproducible H<sub>2</sub> generation ability is the anatase TiO<sub>2</sub>-500-1. There are some indications that TiO<sub>2</sub>-500-Pd may also generate some H<sub>2</sub>, but the results were not reproducible to claim that this material is a reliable H<sub>2</sub> source with visible light (note error bars in Fig. 5B).

From results reported here, it is clear that regeneratable electrospun titania fibers are good catalysts for metal reduction (as shown in the

catalyst synthesis) as well as H<sub>2</sub> generation in the presence of organic compounds, a characteristic that is attractive for water purification strategies in flow systems.

### 3.3. Mechanism of photocatalysis

Based on the above experimental results, a possible mechanism of H<sub>2</sub> evolution using the decorated fibers is proposed and shown in Scheme 2.

Under UV light excitation, the photogenerated electrons in the TiO<sub>2</sub> conduction band are trapped by Pd or Co, delaying the electron-hole recombination process and thus favouring H<sub>2</sub> production Scheme 2A. In the case of the fibers decorated with a Pc (complex **1**), the Pc has a dual role wherein it acts as a sensitizer donates electrons to TiO<sub>2</sub> following the absorption of visible light and leaving behind photogenerated vacancies in the highest occupied molecular orbital (HOMO). This characteristic is reminiscent of Au@CeO<sub>2</sub> that generates H<sub>2</sub> with EDTA as SED [46]. Thus excited dye and possibly PdNP inject electrons into the conduction band of the TiO<sub>2</sub> thus enabling hydrogen formation. In all our examples, methanol acts as a sacrificial electron donor forming formaldehyde as part of the same process. Given the exceptional electrophilic properties of the TiO<sub>2</sub> hole [14] we anticipate that many molecules that are present in water streams as contaminants will be degraded by processes similar to that in Scheme 2 where methanol acts as a surrogate contaminant.

## 4. Conclusion

The work reported here shows that decorated TiO<sub>2</sub> fibers are excellent catalysts for SED decomposition and hydrogen generation. In our case we have used methanol as a convenient SED in order to test catalyst performance, but our earlier work shows that similar reactivity can be observed with many other organic substrates –including some, such as acetonitrile, that can hardly be regarded as typical SEDs [16]. Thus, we expect these materials to perform well for water remediation applications where typical contaminants may include household pollutants and pharmaceuticals. In contrast to typical powder titania catalysts, the materials prepared here (see Fig. 1) are robust paper-like catalysts that can be easily manipulated. They can be readily cut with scissors into any desirable shape, and even in our small-scale production, the initial bare samples were the size of a conventional letter size page. In summary, not only are the new catalysts excellent for the decomposition of organic matter and the production of hydrogen, they are also robust, easy to shape into desired macroscopic morphology and hold promise for flow applications.
