3 26 **Abstract**
4
5
6
7

8 28 *Objective:* Muscle co-activation has been shown to be elevated in individuals with knee
9
10 29 osteoarthritis (KOA) during gait. Comparisons of muscle co-activation across different
11
12 30 activities of daily living such as stair negotiation has yet to be explored. The aim of the study
13
14 31 was to explore muscle co-activation across different activities of daily living in patients with
15
16 32 KOA.
17
18
19 33

20
21 34 *Methods:* Muscle co-activation was assessed in 77 symptomatic KOA participants (age
22
23 35 62.5±8.1years; bodymass index 29.4±9.0kg/m²; gender 48/29 female/male) using
24
25 36 electromyography (EMG), during a series of walking, stair negotiation (ascent, descent) and
26
27 37 sit-to-walk activities. EMG was recorded from 7 sites, medial/lateral gastrocnemius, biceps
28
29 38 femoris, semitendinosus, vastus lateralis/medialis and rectus femoris and normalised to
30
31 39 maximal voluntary isometric contraction. Correlation was used to assess the consistency of
32
33 40 co-activation across activities. Repeated measures ANOVA assessed the muscle combination
34
35 41 by activity differences.
36
37
38
39
40
41
42

41
42 43 *Results:* Muscle co-activation was highest during stair ascent. When comparing muscle
43
44 44 combinations within the same activity correlations ranged from $r=0.003-0.897$ of which 80%
45
46 45 of combinations were significant. Between activities muscle co-activation was significantly
47
48 46 different ($P<0.05$). Medial:lateral muscle co-activation was higher than
49
50 47 hamstrings:quadriceps across activities.
51
52
53
54
55
56
57
58
59
60

48

1
2
3 49 *Conclusion:* Two muscle co-activation strategies were observed during activities of daily
4
5 50 living in patients with KOA to maintain stability. Muscle co-activation was higher during
6
7 51 more challenging activities, particularly when the joint is accepting load. Medial:lateral
8
9 52 muscle co-activation was higher than hamstrings:quadriceps whereby medial:lateral co-
10
11 53 activation is thought to be a stabilisation mechanism whilst hamstrings:quadriceps responds
12
13
14 54 to knee flexion moments, suggesting different muscle combinations may have different
15
16 55 roles in responding to joint demand.

3 59 **Significance and Innovations**
4

- 5 60 • The same patients demonstrated consistently high or low muscle co-activity across all
6
7 61 muscle combinations.
8
9
10 62 • Muscle co-activation was significantly different across activities, whereby muscle co-
11
12 63 activation was higher during more challenging activities e.g. stair negotiation than less
13
14 64 challenging activities e.g. gait.
15
16
17 65 • Neither overall nor selective muscle co-activation strategies were prominent, whereby
18
19 66 it appears both muscle co-activation strategies modulate in unison to promote joint
20
21 67 stability.

68 Introduction

69

70 Individuals with knee osteoarthritis (KOA) exhibit altered movement patterns (i.e. reduced
71 knee flexion; altered knee stiffening) compared to healthy controls (1–6), as a result of
72 structural changes, pain, muscle weakness and a loss of proprioception (7). Muscle
73 activation is controlled by two mechanisms: feedforward based on cognitive control; and
74 feedback responding to changes detected by joint receptors (mechanoreceptors;
75 proprioceptors) (8). These altered movement patterns have been associated with high joint
76 loads; loss of joint stability; and the inability of the musculature to provide stability (9–11).

77

78 Muscle co-activation (simultaneous coordinated agonist and antagonist muscle activity) is
79 thought to be a major mechanism for joint stabilisation, load distribution and movement
80 control during gait in KOA (1–3,5–7,11–17). Baratta et al (9) suggested muscle co-activation
81 is necessary to aid the ligaments in maintaining joint stability; distributing joint surface
82 pressure and regulating joint mechanical impedance. In healthy young individuals and KOA,
83 two muscle co-activation strategies have been identified. Overall muscle co-activation, is
84 considered as high muscle co-activation across all muscle combinations surrounding the
85 joint (18). Selective muscle co-activation involves high muscle co-activation in specific, but
86 not all muscle combinations, (e.g. agonist:antagonist (2,3,18), or medial:lateral (3,19)
87 combinations, but not both). In KOA high levels of muscle co-activation are thought to
88 stabilise the knee in the absence of sufficient stabilisation from the passive-restraints
89 system (20). This strategy has been associated with increased joint contact pressures and
90 maybe a risk factor for cartilage degeneration and KOA disease progression (1–3,5,6,11–
91 14,20,21).

1
2
3 92
4
5 93 It is well established that during walking, individuals with KOA demonstrate higher muscle
6
7 94 co-activation than controls (1,2,4,12,14–17,21) in anterior-posterior (1,2,12,14–17,21) and
8
9 95 medio-lateral (1,17) muscle combinations. This has been reported during specific phases of
10
11 96 gait (1,2,4,13,14,17,21) and the entire gait cycle (3–6,12,15,19,22). Schmitt and Rudolph (1)
12
13
14 97 found that as the knee prepares to accept and accepts weight, high anterior-posterior co-
15
16 98 activation stabilised the joint. During progression from double-limb to single-limb-support,
17
18 99 the knee becomes increasingly unstable and high muscle co-activation across all muscle
19
20
21 100 combinations is needed as a stabilisation mechanism (1). DeMont (23,24) also suggested
22
23 101 control of the knee position during dynamic movement may be dependent on muscle
24
25 102 activation prior to a stress occurring, emphasising the importance of exploring muscle co-
26
27 103 activation prior to heel strike during dynamic activities. For other activities of daily living
28
29 104 (ADL) very little evidence of muscle co-activation in individuals with KOA exists. Two studies
30
31 105 looking at stair negotiation found conflicting results. Childs et al. (2) found high tibialis
32
33 106 anterior:gastrocnemius co-activation in individuals with KOA, whilst Hortobágyi, et al. (14)
34
35 107 found there was no difference between KOA and controls. When activities were grouped,
36
37 108 individuals with KOA had higher biceps femoris:vastus lateralis co-activation. Patsika et al.
38
39 109 (25) found higher biceps femoris muscle activity and no difference in the vastus lateralis
40
41 110 between individuals with KOA and controls during sit-to-stand. Bouchouras et al. (4) also
42
43 111 found significantly higher biceps femoris:vastus lateralis co-activation during sit-to-stand
44
45 112 compared to controls. In healthy individuals, it would be expected that during more
46
47 113 challenging activities (i.e. stair negotiation) requiring higher muscle activation, muscle co-
48
49 114 activation would be higher. In individuals with neuromuscular deficits such as those with
50
51 115 KOA, this may not be true. This may have implications for rehabilitation (i.e. limit tasks
52
53
54
55
56
57
58
59
60

1
2
3 116 which can be undertaken). It is therefore important to understand muscle co-activation
4
5 117 strategies across different ADL and across different muscle combinations.
6

7
8 118

9
10 119 It has been suggested that agonist:antagonist, especially hamstrings:quadriceps co-
11
12 120 activation increases joint stiffness, where it's primary role is to influence anterior tibial shear
13
14 121 force and internal rotation (1,2,26–28). The vastii muscles have however been suggested to
15
16 122 be general joint stabilisers (26,27), whereby medial:lateral co-activation is thought to
17
18 123 respond to joint space narrowing, and instability, increasing joint stiffness and joint load
19
20
21 124 (2,3,26,27). This raises questions about co-activation in KOA. Specifically, do the same
22
23 125 people consistently demonstrate the highest muscle co-activation across different activities
24
25 126 and muscle groups (e.g. high positive correlation between agonist:antagonist and
26
27 127 medial:lateral muscle co-activation across all activities)? Alternatively, do different
28
29
30 128 individuals exhibit high muscle co-activation during different activities or muscle
31
32 129 combinations (e.g. high medial:lateral and low agonist:antagonist muscle co-activation
33
34 130 during stair negotiation, and low medial:lateral and high agonist:antagonist muscle co-
35
36 131 activation during gait).
37
38
39

40 132

41
42 133 The purpose of this study was to explore muscle co-activation patterns across different ADL
43
44 134 and investigate specific areas of muscle co-activation during different phases of gait. It was
45
46 135 hypothesised that 1) for a specific activity, patients will demonstrate high muscle co-activity
47
48 136 across all muscle combinations; 2) muscle co-activation will be higher in the medial:lateral
49
50 137 than agonist:antagonist muscle combinations in patients with KOA; 3) muscle co-activation
51
52 138 will be higher during more challenging activities (e.g. stair descent) compared to less
53
54 139 challenging activities (e.g. gait).

12
13
14 145 Data analysis presented here is part of the NEKO study (NCT02314715,
15
16 www.clinicaltrials.gov). A convenience sample of adults (40 years or over), with doctor-
17 146 diagnosed unilateral/bilateral KOA, with self-reported knee pain, stiffness lasting
18
19 147 <30minutes and confirmed by ultrasound and/or magnetic resonance imaging (data not
20
21 148 presented), were recruited through rheumatology clinics; general practitioner practices; and
22
23 149 a local newspaper advert. Participants were excluded if they had any current neuromuscular
24
25 150 skeletal injury or disease, knee replacement, knee surgery in the past year, steroid injections
26
27 151 in the past 3 months or severe co-morbidity which would limit participation in the study.

28
29 152 All participants gave written informed consent to participate in the study. The assessment
30
31 153 protocol was approved by the West of Scotland Research Ethics Committee (ref
32
33 154 13/WS/0146) and Glasgow Caledonian University (ref HLS12/86) and carried out in
34
35 155 compliance with the Declaration of Helsinki.
36
37 156

38
39 15740
41 158 *Electromyography and muscle co-activation*42
43 159

44
45 160 Wireless surface electrodes (99% silver, 4 5x1mm bar 'Trigno' sensors, fixed inter-electrode
46
47 161 distance 10mm, Delsys, Boston, USA) were placed over the belly of the vastus medialis
48
49 162 (VM); rectus femoris (RF); vastus lateralis (VL); semitendinous (ST); biceps femoris (BF);
50
51 163 medial and lateral gastrocnemius (MG; LG) muscles of the test leg (6,12,29). The test leg was

1
2
3 164 defined as the most symptomatic knee based on self-report. The electrode placement was
4
5 165 in accordance with surface electromyography for the non-invasive assessment of muscles
6
7 166 (SENIAM) recommendations (30,31). The area was shaved, lightly abraded and cleaned with
8
9 167 alcohol. Isolated contractions assessed electromyography (EMG) recordings. The raw signal
10
11 168 was passed through a Trigno differential amplifier, input impedance 10,000M Ω , CMRR
12
13 169 >80dB, gain 1,000 with a bandwidth of 20Hz-450Hz. EMG signal was recorded with a 16-bit
14
15 170 analogue-to-digital converter (PCI-DAS6402/16, Measurement computing corporation,
16
17 171 Massachusetts, USA), at a sampling rate of 2400Hz. All EMG and force data were collected in
18
19 172 Qualysis Track Manager (version 2.7-2.9, Qualysis Motion Capture Systems, Sweden) and
20
21 173 processed in Spike2 (version 2.7.10, Cambridge Electronic Design Ltd, Cambridge, UK).
22
23
24
25
26
27

174

175 *Measures of activities of daily living*

176

177 Participants performed a series of ADL tasks in the following order; stair ascent and stair
178 descent, walking, and sit-to-walk transitions, during a single visit to the human performance
179 laboratory at Glasgow Caledonian University. The number of trials performed for each
180 activity as stated in the protocol was a pragmatic decision to enable high-quality data to be
181 collected while safeguarding patients against high levels of fatigue.
182

183

184 Participants performed three stair ascent and descent trials using a four-step instrumented
185 staircase with a force plate (Kistler, 9286BA, Switzerland) embedded in the second step,
186 aligned with a second Kistler force plate in the walkway. Participants ascended the stairs,
187 turned and descended, ensuring the test leg landed on both force plates (walkway and
second step). A successful trial was defined as the entire foot landing within the boundaries

1
2
3 188 of the force plate with no obvious signs of targeting the plate. The use of handrails was
4
5 189 permitted if required, step-over-step (alternate leg on each step) was preferred; however,
6
7 190 when this was not possible step-by-step (both legs on the same step with test leg as lead
8
9 191 leg) was permitted.

11
12 192

13
14 193 Participants performed seven successful walking trials at a self-selected walking speed. A
15
16 194 successful trial was defined as above and within $\pm 10\%$ of movement time (Brower timing
17
18 195 system, Draper, Utah, USA).

20
21 196

22
23 197 A standard armchair (height 48cm) was placed on the walkway next to the force plate.

24
25 198 Participants sat with their back against the chair and test leg on the force plate, they were
26
27 199 instructed to stand up, walk 3.6m before turning and returning to a seated position. The use
28
29 200 of the chair arms was permitted if required. For the purpose of this analysis, the stance
30
31 201 phase (onset of force to toe-off), from three sit-to-walk trials was used.

32
33 202

34
35 203 For all activities, the stance phase was analysed, defined as initial contact (ground reaction
36
37 204 force exceeded 20N) to toe-off (ground reaction force fell below 20N). During walking the
38
39 205 stance phase was also split into four sub-phases; loading (0-14.9% of stance), early-stance
40
41 206 (15-39.9%), mid-stance (40-59.9%) and late-stance (60-100%) with an additional pre-stance
42
43 207 phase (-150ms to initial contact) (17). Stair ascent and descent were each split into two sub-
44
45 208 phases; walk-to-stair transition (stance on the floor force plate) and continuous (stance on
46
47 209 the force plate embedded in the stairs).

48
49 210
50
51
52
53
54
55
56
57
58
59
60

1
2
3 211 Participants performed a series of maximal voluntary isometric contractions (MVIC), using
4
5 212 an isometric dynamometer (Biodex 4 Pro, Biodex Medical Systems Inc, New York, USA).
6
7 213 Participants were seated with their knee and hip flexed at 50deg and 90deg respectively.
8
9 214 Following a series of warm-up contractions, participants performed 3 flexion/extension
10
11 215 MVIC's lasting 3s with 30s rest for the hamstrings and quadriceps respectively. For the
12
13 216 gastrocnemius participants were seated with their knee at full extension and foot in
14
15 217 anatomically neutral. Following a series of warm-up contractions, participants performed a
16
17 218 series of 3 plantarflexion MVIC's lasting 3s with 30s rest. Data was analysed over a 500ms
18
19 219 window: 250ms either side of peak force for hamstrings and quadriceps and 250ms either
20
21 220 side of peak EMG amplitude for gastrocnemius.
22
23
24
25

221

222 *Symptom severity*

223 Participants completed the knee injury and osteoarthritis survey (KOOS) (32) and self-
224 reported the duration of their symptoms.

225

226 *Data Management*

227

228 EMG data was Butterworth 4th order zero-lag bandpass filtered at 20-450Hz. The average
229 root mean squared amplitude (RMS_{amp}) was calculated for the stance phase, subsequent
230 sub-phases defined above and normalised to MVIC RMS_{amp} (33–35). RMS_{amp} was chosen as
231 it is suggested to be more robust and directly linked to electrical power, having more
232 physiological significance over linear envelope (33,36). MVIC's were used for normalisation
233 over peak dynamic amplitude because it is believed that MVIC's provide an estimate of
234 neuromuscular control and information about muscle activation enabling individual

235 variation which precludes direct comparison to be taken into account (33,34,36). In
 236 individuals with KOA normalisation to MVIC has been used to understand neuromuscular
 237 control alterations (3,35,37–39) and serves to provide a physiological reference (40).

238

239 Muscle co-activation was calculated using RMS_{amp} normalised to MVIC, normalised RMS_{amp}
 240 data was used to calculate muscle co-activation using equation (1), where $lowerEMG_i$ and
 241 $higherEMG_i$ are respectively the lowest and highest RMS_{amp} at sample i , division by 100
 242 takes the average across the normalised interval (41). Muscle co-activation strategies were
 243 explored using the following muscle groups: quadriceps ([Q] VL; RF; VM):gastrocnemius ([G]
 244 MG; LG); gastrocnemius(G):hamstrings ([H] ST; BF) hamstrings(H):quadriceps(Q); and medial
 245 ([M] VM; ST; MG):lateral ([L] VL; BF; LG) and muscle pairs: VL:VM; ST:BF; MG:LG. Muscle
 246 groups involving multiple muscles, the mean RMS for the muscles involved was used. To
 247 explore agonist:antagonist versus medial:lateral muscle co-activation the following muscle
 248 combinations were used: H:Q and VL:VM.

249

$$250 \quad \text{Co-activation Index} = \frac{\sum_{i=1}^{100} \frac{lowerEMG_i}{higherEMG_i} (lowerEMG_i + higherEMG_i)}{100} \quad (1)$$

251

252 *Statistical Analysis*

253

254 Descriptive statistics including means, standard deviations, and frequencies of the
 255 demographics were determined. Skewness, kurtosis, and boxplots were obtained to
 256 examine the distribution and identify outliers for all variables. Hierarchical sensitivity
 257 analysis was performed with 1) all data; 2) extreme outliers ($>3*$ interquartile range (IQR))

1
2
3 258 removed; 3) all outliers ($>1.5 \times \text{IQR}$) removed; 4) all outliers and device users removed ('valid
4
5 259 data'); 5) valid data with $1.5 \times \text{IQR}$ outliers associated with low MVIC or pain during MVIC
6
7 260 included. Device users were defined as individuals who used the stairs handrails and/or a
8
9 261 walking-aid whilst performing the ADL tasks. Once extreme outliers were removed some
10
11 262 variables remain insignificant whilst others became significantly different between
12
13 263 individuals with KOA and controls (data not presented), this did not change when further
14
15 264 outliers were removed (42). The main analysis was run with only extreme ($3 \times \text{IQR}$) outliers
16
17 265 removed. Sensitivity analysis was performed with and without device users; there was no
18
19 266 difference between device users and non-device users.
20
21
22
23
24
25

26 268 Repeated measures ANOVA followed up with Bonferroni *post hoc* test was performed to
27
28 269 compare muscle co-activity within each activity. Pearson's correlations between muscle co-
29
30 270 activation combinations within the same activity, and partial correlations controlling for
31
32 271 muscle strength and age assessed hypothesis 1 (muscle co-activation would be high across
33
34 272 all muscle combinations within a given activity). Correlation strength was defined as $r < 0.1$
35
36 273 no association; $r = 0.1 - 0.29$ weak; $r = 0.3 - 0.49$ moderate; $r > 0.49$ strong association (43).
37
38 274 Hypothesis 2 (muscle co-activation will be higher in the medial:lateral than
39
40 275 agonist:antagonist pairs) was assessed with paired sample T-Tests using VL:VM and H:Q
41
42 276 combinations. The VL:VM co-activation provides a clear metric for medial:lateral co-
43
44 277 activation to provide neuromuscular control of the knee joint, as the vastii muscles were
45
46 278 general joint stabilisers (26). Repeated measures ANOVA (muscle co-activation-by-activity)
47
48 279 followed up with Bonferroni *Post hoc* test addressed hypothesis 3 (muscle co-activation will
49
50 280 be higher during more challenging activities). All statistical analysis was conducted using
51
52 281 SPSS (version 22.0 Chicago, USA) with alpha set at 0.05.

282

283 **Results**

284

285 A total of 77 individuals with KOA were recruited from Rheumatology Clinics (N=15), general
286 practitioner practices (n=4) and a local newspaper advert (N=58) (Table 1), 13 (17%) people
287 had missing data for the stairs.

288

289 *Gait*

290 During gait, VL:VM demonstrated higher muscle co-activation than ST:BF during pre-stance,
291 loading, early-stance, and MG:LG during loading. During mid-stance, late-stance and overall-
292 stance MG:LG was higher than ST:BF and VL:VM. Medial:lateral co-activation was higher
293 than Q:G, G:H during pre-stance and loading; H:Q, G:H during early-stance, mid-stance, and
294 overall-stance; H:Q, Q:G, G:H during late-stance (waveform data in supplement A).

295

296 Within the same phase of walking, correlations between muscle co-activation combinations
297 ranged from no-association to strong positive associations (Figure 1; Supplement B). Pre-
298 stance ranged from $r=0.264$ ($P=0.025$, ST:BF-VL:VM) to $r=0.897$ ($P<0.001$, H:G-Q:G), loading
299 range from $r=0.070$ ($P=0.557$, H:G-VL:VM) to $r=0.682$ ($P<0.001$, H:Q-ST:BF) of which 87% of
300 combinations were significant, for early-stance $r=0.296$ ($P=0.011$, H:Q-MG:LG) to $r=0.739$
301 ($P<0.001$, H:G-H:Q), mid-stance ranged $r=0.105$ ($P=0.374$, MG:LG-VL:VM) to $r=0.759$
302 ($P<0.001$, Q:G-VL:VM) of which 73% of combinations were significant, late-stance ranged
303 from $r=0.073$ ($P=0.547$, H:Q-MG:LG) to $r=0.708$ ($P<0.001$, Q:G-VL:VM) of which 87% of
304 combinations were significant, and overall-stance ranged from $r=0.159$ ($P=0.191$, H:Q-
305 MG:LG) to $r=0.721$ ($P<0.001$, H:Q-H:G and H:Q-ST:BF) of which 93% of combinations were

1
2
3 306 significant. The strength of the associations decreased when controlling for age and muscle
4
5 307 strength.

6
7 308

9
10 309 Muscle co-activation was significantly higher for VL:VM than H:Q for loading ($P=0.008$),
11
12 310 early-stance ($P<0.001$), mid-stance ($P<0.001$), late-stance ($P<0.001$) overall-stance
13
14 311 ($P<0.001$), there was no difference for pre-stance ($P=0.319$, Figure 2).

15
16 312

17
18
19 313 *Stair negotiation*

20
21 314 Medial:lateral gastrocnemius co-activation was higher than VL:VM during stair ascent
22
23 315 transition (SUT), and continuous stair descent (SDC), while MG:LG and VL:VM were similar
24
25 316 and higher than ST:BF during continuous stair ascent (SUC) and descent transition (SDT).
26
27 317 Medial-lateral co-activation was higher than H:Q, H:G during SUT, SUC, and SDC; Q:G during
28
29 318 SUT and SDT. During SDC Q:G was similar to H:G; M:L, and higher than H:Q.

30
31 319

32
33 320 Within the same phase of stair negotiation, correlations across muscle co-activation ranged
34
35 321 from no association to strong positive associations (Figure 1, supplement B). Stair ascent
36
37 322 transition ranged from $r=-0.004$ ($P=0.976$, MG:LG-VL:VM) to $r=0.850$ ($P<0.001$, H:G-ST:BF) of
38
39 323 which 60% of combinations were significant, SUC ranged from $r=0.079$ ($P=0.548$, Q:G-
40
41 324 MG:LG) to $r=0.784$ ($P<0.001$, H:G-H:Q) of which 60% of combinations were significant.

42
43 325 During SDC correlations ranged from $r=-0.006$ ($P=0.984$, H:Q-MG:LG) to $r=0.816$ ($P<0.001$
44
45 326 H:Q-ST:BF) with 60% of combinations significant, whilst SDT ranged from $r=0.003$ ($P=0.984$,
46
47 327 ST;BF-MG:LG) to $r=0.722$ ($P<0.001$, H:Q-ST:BF) of which 60% of combinations were
48
49 328 significant. The strength of the associations decreased when controlling for age and muscle
50
51 329 strength.

52
53
54
55
56
57
58
59
60

330

331 Muscle co-activation was significantly higher for VL:VM than H:Q across all phases of stair
332 negotiation ($P<0.001$; Figure 2).

333

334 *Sit-to-walk*

335 During sit-to-walk VL:VM demonstrated higher muscle co-activation than ST:BF and MG:LG,
336 whilst M:L was higher than H:Q, Q:G and H:G. Sit-to-walk demonstrated a weak ($r=0.251$,
337 $P=0.032$, H:Q-MG:LG) to strong associations ($r=0.727$, $P<0.001$, H:Q-H:G; Figure 1;
338 Supplement B). Muscle co-activation was higher in VL:VM than H:Q ($P<0.001$) during sit-to-
339 walk (Figure 2).

340

341 *Muscle co-activation across activities*

342 Muscle co-activation was significantly different within the same muscle co-activation
343 combination across activities and phases ($P<0.001$) for all muscle co-activation combinations
344 (Figure 3). Muscle co-activation was significantly ($P<0.05$) different across 65.5% (H:Q);
345 61.8% (H:G); 63.6% (Q:G); 70.9% (M:L); 74.5% (VL:VM); 47.2% (ST:BF); 72.7% (MG:LG) of
346 activity combinations. Pre-stance was significantly different to loading; early-stance; overall-
347 stance; sit-to-walk and stair negotiation across all muscle combinations except ST:BF. Pre-
348 stance was significantly different to loading; mid-stance and late-stance for ST:BF. Mid-
349 stance and late-stance were different to loading; overall-stance; sit-to-walk for all muscle
350 combinations. Overall-stance was different to sit-to-walk (H:G) and SUC (all combinations
351 except H:G; ST:BF); sit-to-walk was different to SUC (all combinations except ST:BF) and stair
352 ascent and descent phases were also different to each other for all combinations except
353 ST:BF.

1
2
3 3544
5 355 **Discussion**6
7 356

8
9 357 The results indicate that muscle co-activation was positively correlated across different
10
11 358 muscle combinations within the same activity. Medio-lateral co-activation within the
12
13 359 quadriceps was higher than anterior-posterior co-activation across all activities in KOA.
14
15 360 Muscle co-activation was higher during more challenging activities (stair negotiation) than
16
17 361 less challenging activities (gait).
18

19
20
21 362

22
23 363 Investigations into muscle co-activation in KOA typically focus on walking. This study aimed
24
25 364 to explore muscle co-activation across different ADL, during which different muscle co-
26
27 365 activation strategies were observed. Overall muscle co-activation was deployed when the
28
29 366 limb is preparing to, and accepts weight and starts to transition towards single limb support.

30
31 367 It appears that overall muscle co-activation is a strategy adopted when the limb is least
32
33 368 stable, in more vulnerable positions requiring all muscles to activate simultaneously to
34
35 369 stabilise the joint. During transitions from single-to-double limb support and when increased
36
37 370 muscle force is required to propel the body from a flexed position into extension (mid-
38
39 371 stance and late-stance; sit-to-walk; stair ascent) selective muscle co-activation was utilised.

40
41 372 Specifically high muscle co-activation in MG:LG and VL:VM which are thought to act as joint
42
43 373 stabilisers, contribute towards rotational moments or increase compressive loads to
44
45 374 facilitate moment generation needed to direct ground reaction forces, and potentially
46
47 375 increase medial joint stability (11,26,27,44,45). Our results demonstrated neither overall nor
48
49 376 selective muscle co-activation was prominent, with a combination of both strategies
50
51 377 utilised. Mills et al. (11) a systematic review of 14 papers, highlighted that during walking

1
2
3 378 specific muscle co-activation is believed to play a role in distributing loads, whilst Lloyd and
4
5 379 Buchanan (18) found in their modelling study that specific muscle co-activation (H:Q)
6
7 380 contributed to muscular support in response to static valgus-varus loads. These results
8
9 381 suggest that both muscle co-activation strategies are modulated throughout different
10
11 382 phases of walking or other activities to increase joint stability; distribute joint loads and
12
13 383 support joint moments at the potential cost of increased compressive loads.
14
15
16
17 384

18
19 385 Within the same activity, the same patients demonstrated high or low muscle co-activity
20
21 386 across all muscle combinations. With increasing age and the addition of joint space
22
23 387 narrowing associated with KOA, the passive restraints (e.g. ligaments) become increasingly
24
25 388 lax (39,44). To prevent lateral joint opening and the transfer of load medially higher
26
27 389 antagonist muscle force is required (46). Higher antagonist muscle activation is thought to
28
29 390 increase joint stiffness (46), however, the ability to adopt movement strategies which
30
31 391 remain normal is lost with muscle weakness (39). Alterations in muscle co-activation
32
33 392 strategies may therefore, try and accommodate this lack of joint stability. Individuals with
34
35 393 selective high muscle co-activation may be at an increased risk of disease progression as a
36
37 394 result of high joint loads combined with high joint pressures associated with high muscle co-
38
39 395 activation.
40
41
42
43
44
45

46 397 VL:VM co-activation was higher than H:Q in individuals with KOA across all activities except
47
48 398 pre-stance. H:Q co-activation increases joint stiffness to counteract joint instability (2).
49
50 399 Hamstrings activation is thought to increase joint stiffness and reduce loads on the anterior
51
52 400 cruciate ligament by reversing the shear force on the tibia counterbalancing the main knee
53
54 401 flexion moment, at the expense of increased patellofemoral and tibiofemoral load (28).
55
56
57
58
59
60

1
2
3 402 VL:VM co-activation has been suggested to be a response to joint space narrowing,
4
5 403 increased joint stiffness and joint surface loading (2,3,19,37,47). Flaxman et al., also
6
7 404 identified the vastii muscles as general joint stabilisers bracing the knee (26,27). When
8
9 405 combined with increased joint contact pressures associated with high muscle co-activation,
10
11 406 this may increase the risk for cartilage degeneration (1–3,6,12–14,18,19,21). Hodges et al.
12
13 407 (48) found that increased duration of medial (vastus medialis:semimembranosus) co-
14
15 408 activation was associated with medial cartilage loss in medial KOA, whilst Zeni et al (12)
16
17 409 found high medial co-activation controlled medial laxity and instability in medial KOA.
18
19 410 Lateral (vastus lateralis:biceps femoris) co-activation was inversely related with medial
20
21 411 cartilage loss in KOA (48), and is thought to unload the medial compartment (3,6,15,17).
22
23 412 According to findings from Bae et al (49), tibiofemoral OA is either confined to the medial
24
25 413 compartment or generalized over the medial and lateral compartments. Several studies in
26
27 414 medial and generalised KOA are in support of selective lateral activation (3,6,15,17),
28
29 415 however, others do not (1,44,45). These results appear to be consistent with medial and
30
31 416 generalised KOA across the literature. Three studies investigated muscle co-activation and
32
33 417 included medial KOA patients only, with mixed results. Rudolph et al (39) and Lewek et al
34
35 418 (45) found higher medial activation whilst Lewek et al (37) demonstrated high lateral muscle
36
37 419 co-activation. Including both medial and generalised KOA in this study may dilute any
38
39 420 compartmental differences if they exist however further research is required to understand
40
41 421 muscle co-activation differences between medial tibiofemoral and generalised disease.
42
43
44
45
46
47
48
49
50

51 423 Muscle co-activation across activities was significantly different. It was hypothesised that
52
53 424 muscle co-activation would be higher during more challenging activities such as stair
54
55 425 negotiation compared to less challenging activities such as gait. Muscle co-activation was
56
57
58
59
60

1
2
3 426 higher during stair negotiation than overall-stance and sit-to-walk, where overall-stance was
4
5 427 higher than sit-to-walk. This is potentially due to a combination of greater joint instability
6
7 428 and muscle force required to perform more challenging activities, whereby knee joint
8
9 429 stability is required to propel the body up each step or control the lowering of the body
10
11 430 down each step. During pre-stance the results demonstrated higher Q:G, and similar Q:H
12
13 431 activity to Schmitt and Rudolph (1), where Q:G, G:H, and MG:LG are low whilst Q:G, M:L,
14
15 432 VL:VM, ST:BF appear to be increasing in preparation to accept load (1,3) and slow the
16
17 433 acceleration of the joint. During loading our results were higher compared to the literature,
18
19 434 and higher than pre-stance except for MG:LG which is in keeping with the literature showing
20
21 435 a peak in quadriceps activity (3,6). Additionally, high medial:lateral co-activation during
22
23 436 loading was found which is similar to Heiden et al (17). During early-stance all combinations
24
25 437 were lower than loading in line with Schmitt and Rudolph (1), whilst M:L remained higher
26
27 438 than other combinations (17). During Mid- and late-stance no studies using the same
28
29 439 equation MG:LG which increased, peaking during late-stance. Muscle co-activation was
30
31 440 higher during sit-to-walk across all combinations compared to gait except for loading and
32
33 441 overall-stance, stair ascent was higher than sit-to-walk and gait except for loading and
34
35 442 overall stance. During continuous stair ascent muscle co-activation was higher than ascent
36
37 443 transition for ST:BF and MG:LG. Muscle co-activation during stair descent was generally
38
39 444 higher than gait and lower than continuous ascent and ascent. During more biomechanically
40
41 445 challenging activities requiring greater muscle activation elevated co-activation is expected.
42
43 446 This was shown in KOA patients in this study.
44
45
46
47
48
49
50

51 447

52
53 448 This study has a number of strengths and limitations. Firstly it is a relatively large
54
55 449 convenience sample (N=77) with substantial sensitivity analysis performed prior to and
56
57
58
59
60

1
2
3 450 during the statistical analysis. We did not screen or grade participants for radiographic
4
5 451 disease severity making comparisons with previous literature difficult. MVIC's were
6
7 452 performed for the hamstrings and quadriceps however reference contractions were
8
9 453 performed for the gastrocnemius to prevent discomfort to the patient. During stair
10
11 454 negotiation and sit-to-walk transition participants were permitted to use the handrails, step-
12
13 455 by-step stair negotiation style, and chair arm. Whilst this showed muscle co-activation
14
15 456 during normal daily living, this meant movement was not standardised across the entire
16
17 457 sample. Sensitivity analysis indicated that this did not affect the results presented here.
18
19 458 Other studies which looked at muscle co-activation during stair negotiation did not allow
20
21 459 the use of handrails. Muscle co-activation was higher in the study participants compared to
22
23 460 the values reported for individuals with KOA in the literature (2,15,37,38). It is unclear why
24
25 461 muscle co-activation values were so high compared to the literature possible explanations
26
27 462 include: varying disease severity, participant demographics. Differences in signal processing
28
29 463 as the studies which used the same equation and normalisation methods used linear
30
31 464 envelope to process their data rather than RMS, whilst others used difference co-activation
32
33 465 equations, normalisation methods, different time epochs over which the data was analysed.
34
35 466 Alternatively, low muscle activation during MVIC as a result of not fully activating the
36
37 467 musculature or really low muscle activation may elevate the normalised EMG.
38
39
40
41
42
43
44

468

46 469 To conclude, muscle co-activation patterns appear to be high across all muscle combinations
47
48 470 within the same activity. Higher muscle co-activation was observed during more challenging
49
50 471 activities which require greater stability. Whilst neither overall nor selective muscle co-
51
52 472 activation was prominent it appears they modulate in unison to maintain joint stability and
53
54 473 respond to the demands upon the joint. Whilst high muscle co-activation appears to be a

1 **Tables**

Table 1: Patient demographics and activities of daily living data presented as means (SD)

Characteristic	KOA (n = 77)
Age, years	62.5 (8.1)
Females, %	48 (62%)
Height, m	1.66 (0.11)
Body mass, kg	81.5 (19.4)
BMI, kg/m ²	29.4 (6.0)
Duration of symptoms, yrs	9.3 (9.2)
KOOS pain	56.8 (17.6)
KOOS symptoms	54.7 (19.4)
KOOS activities of daily living	65.2 (20.1)
KOOS sports and recreation	33.8 (24.9)
KOOS quality of life	39.1 (21.3)
Activities of daily living	
Walking Speed, m/s	1.05 (0.15)
Walking stick used, Yes (%)	2 (3%)
Chair arm used, Yes (%)	53 (69%)
Stairs walking styles (KOA=64 C=16)	
Ascent, SOS (%)	60 (94%)
SBS (%)	4 (6%)

Descent, SOS (%)	56 (88%)
SBS (%)	8 (12%)
Handrail used, Yes (%)	26 (41%)

KOA = knee osteoarthritis; BMI = bodymass index; SOS = step-over-step; SBS =
step-by-step; KOOS = knee injury and osteoarthritis outcome survey
