In their recent paper, Cui et al. (2020) used a new iteration of their C<sub>3</sub> plant proxy to reconstruct  $p\text{CO}_2$  over the last 23 Ma. The initial version of this proxy used carbon isotope discrimination ( $D^{13}\text{C}$ , calculated as the offset between the  $d^{13}\text{C}$  of plant tissue [ $d^{13}\text{C}_p$ ] and atmospheric CO<sub>2</sub> [ $d^{13}\text{C}_{\text{atm}}$ ]) to estimate paleo-CO<sub>2</sub> (Schubert and Jahren, 2015), but recent work by different research groups has questioned the utility of this proxy (e.g., Kohn, 2016; Stein et al., in press). Previously, we used  $D^{13}\text{C}$  data from *Arabidopsis thaliana* plants grown experimentally under different moisture and  $p\text{CO}_2$  conditions to show that this proxy is strongly impacted by variations in moisture availability and underpredicts  $p\text{CO}_2$  (Lomax et al., 2019). Here, we argue that the new version of the C<sub>3</sub> proxy presented by Cui et al. (2020), which is centered on  $d^{13}\text{C}_p$  rather than  $D^{13}\text{C}$ , suffers from the same shortcomings. Therefore, it is unsuitable for addressing the core question posed in their paper, that is, how  $p\text{CO}_2$  levels in the geological past compare with those both in the present and predicted for the near future.

Using the new  $d^{13}\text{C}_p$  proxy to reconstruct  $p\text{CO}_2$  from our existing *A. thaliana* data set (Jardine and Lomax, 2020; Lomax et al., 2019) shows that, like its predecessor, this proxy underestimates  $p\text{CO}_2$  (Fig. 1A), although the effect is even more pronounced than previously (Fig. 1B). The proxy struggles to successfully predict  $p\text{CO}_2$  for plants grown in >400 ppm conditions, which is particularly problematic because this is the core threshold for assessing whether past  $p\text{CO}_2$  values exceed those of today.  $p\text{CO}_2$  estimates are likely lower in this iteration of the proxy because rather than deriving a new relationship between  $d^{13}\text{C}_p$  and  $p\text{CO}_2$ , Cui et al. (2020) used the model parameters (the A, B and C terms) from their  $D^{13}\text{C}$ :  $p\text{CO}_2$  curve (Schubert and Jahren, 2015). However, the  $d^{13}\text{C}_{\text{anomaly}}$  term of Cui et al. (2020; see their Equations 1 and 2) does not equal the  $D(D^{13}\text{C})$  term of Schubert and Jahren (2015; see their Equations 1 and 4) (Fig. 1C). The result is that  $p\text{CO}_2$  predicted from  $d^{13}\text{C}_p$  is even lower than  $p\text{CO}_2$  predicted from  $D^{13}\text{C}$ , with the downward bias becoming particularly apparent at  $p\text{CO}_2 > 400$  ppm (Fig. 1B).

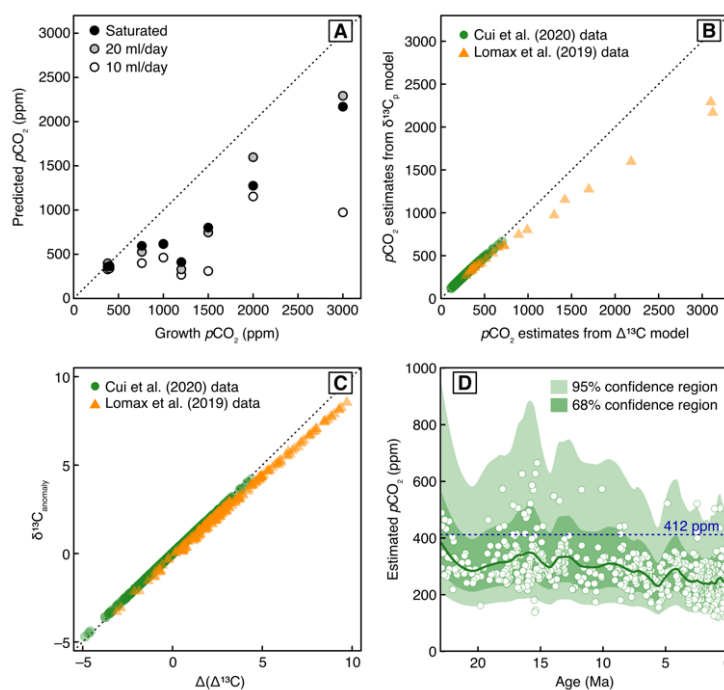

As with the  $D^{13}\text{C}$  version of the C<sub>3</sub> proxy, the new  $d^{13}\text{C}$ -based proxy is impacted by moisture availability, especially at higher  $p\text{CO}_2$  levels (Fig. 1A). This is a critical issue in the timeseries presented by Cui et al. (2020), because hydrological changes are likely to have accompanied  $p\text{CO}_2$ -driven temperature changes, for instance across the mid-Miocene Climatic Optimum, ~17–14 Ma (Loughney et al., 2020). The extent to which the increase in  $p\text{CO}_2$  reconstructed for this time by Cui et al. (2020) (Fig. 1D) is due to increases in moisture availability cannot be evaluated with this proxy, nor can the impact of long-term continental drying through the late Neogene on the overall downward  $p\text{CO}_2$  trend.

Cui et al. (2020) used Monte Carlo resampling to quantify uncertainty in their  $p\text{CO}_2$  reconstruction, and presented these uncertainties via a LOWESS smoother with a 68% confidence interval. A 68% confidence interval represents an abnormally low level of statistical confidence, and is too narrow to robustly determine whether  $p\text{CO}_2$  values in the past exclude today's levels or those of the future. Plotting 95% confidence intervals (and therefore utilizing the usual  $\alpha = 0.05$  level for statistical inference) shows that  $p\text{CO}_2$  values of >500 ppm are entirely consistent with Cui et al.'s reconstruction for much of the last 23 Ma, including in the Pliocene and Pleistocene. The C<sub>3</sub> proxy therefore fails to reject elevated  $p\text{CO}_2$  conditions for the late Neogene and Quaternary, despite the downward biasing in the  $p\text{CO}_2$  estimates themselves (Fig. 1D).

Understanding the relationship between  $p\text{CO}_2$  and global climate is vital for forecasting the response of the climate system to anthropogenic CO<sub>2</sub> emissions. As such,  $p\text{CO}_2$  proxies are essential, but they need to be robust and thoroughly validated. Terrestrial fossil organic carbon may be ubiquitous in sediments, but because of impact of moisture availability on  $d^{13}\text{C}_p$ , and the inadequately derived relationship between  $d^{13}\text{C}_p$  and  $p\text{CO}_2$  used by Cui et al. (2020), we maintain (Lomax et al., 2019) that the C<sub>3</sub> proxy is not suitable for reconstructing  $p\text{CO}_2$  in the geological past.
