**Abstract**

Multi-step ahead inflow forecasting has a critical role to play in reservoir operation and management in Taiwan during typhoons as statutory legislation requires a minimum of 3-hours warning to be issued before any reservoir releases are made. However, the complex spatial and temporal heterogeneity of typhoon rainfall, coupled with a remote and mountainous physiographic context makes the development of real-time rainfall-runoff models that can accurately predict reservoir inflow several hours ahead of time challenging. Consequently, there is an urgent, operational requirement for models that can enhance reservoir inflow prediction at forecast horizons of more than 3-hours. In this paper we develop a novel semi-distributed, data-driven, rainfall-runoff model for the Shihmen catchment, north Taiwan. A suite of Adaptive Network-based Fuzzy Inference System solutions is created using various combinations of auto-regressive, spatially-lumped radar and point-based rain gauge predictors. Different levels of spatially-aggregated radar-derived rainfall data are used to generate 4, 8 and 12 sub-catchment input drivers. In general, the semi-distributed radar rainfall models outperform their less complex counterparts in predictions of reservoir inflow at lead-times greater than 3-hours. Performance is found to be optimal when spatial aggregation is restricted to 4 sub-catchments, with up to 30% improvements in the performance over lumped and point-based models being evident at 5-hour lead times. The potential benefits of applying semi-distributed, data-driven models in reservoir inflow modelling specifically, and hydrological modelling more generally, is thus demonstrated.

Keywords: semi-distributed model, rainfall-runoff model, data-driven model, reservoir inflow, radar rainfall, ANFIS

## 1. INTRODUCTION

Data-driven modelling (Solomatine, 2005; Solomatine and Ostfeld, 2008; Elshorbagy et al., 2010a,b) is a major component of hydroinformatics (Abbott, 1991; 1999; See et al., 2007; Abrahart et al., 2008; Holz et al., 2011), in which emerging technological products, primarily related to developments in computational intelligence and machine learning algorithms, are applied to complex hydrological problems. In data-driven modelling, the responsibility for identifying model structure is largely passed to computer algorithms, that are not constrained by a need for their solutions to conform to fundamental concepts in hydrology (Mount and Abrahart, 2011a). However, stronger calls for greater incorporation of scientific knowledge and understanding in the development of data-driven hydrological models are now starting to be published (e.g. Abrahart et al., 2011) in which it is argued that better representation of catchment processes should result in improved data-driven modelling products that offer more than optimized curve fitting solutions (Mount and Abrahart, 2012).

One of the most popular uses of data-driven models is the prediction of runoff from rainfall e.g. by means of developing a neural network (De Vos, 2012), fuzzy logic (Wang and Altunkaynak, 2012) or genetic programming (Rodríguez-Vázquez et al., 2012) solution that will effectively convert observed input into required output. In this application domain, the importance of capturing the spatial variability of rainfall-runoff processes via distributed and semi-distributed hydrological modelling frameworks is well-known (Beven and O'Connell, 1982; Tetzlaff and Uhlenbrook, 2005; Segond et al., 2007; Younger et al., 2009). The need to account for spatial distribution becomes particularly acute if convective rainfall, with a high degree of spatio-temporal heterogeneity and uncertainty, is the key driver of runoff (e.g. typhoon events). In this context, instrumentational deficiencies (e.g. Molini et al., 2005) and the number, positioning and overall distribution of monitoring stations (e.g. Cheng et al., 2008) present significant challenges for modellers. Indeed, hydrologists have long claimed that the main factor limiting predictive performance of distributed rainfall-runoff models was interpolated input derived from point-based rain gauge data (Berne & Krajewski, 2012). Whilst traditional, Thiessen Polygon (Thiessen, 1911) approaches remain popular (e.g. Rajurkar, et al., 2002; Wu and Chau, 2011), the errors that result are well known (American Society of Civil Engineers, 1996: 50). Thus, better approaches to interpolation of point-based, rain gauge data continue to receive a modest amount of interest from the scientific community e.g. Schiemann et al. (2010), Verworn and Haberlandt (2011), Ly et al. (2011), Wagner et al. (in press). In recent years the availability of

1  
2  
3 spatially-continuous radar rainfall data has led to its widespread utilisation by  
4 hydrologists and inclusion in particular sorts of model (e.g. Schell et al., 1992;  
5 James et al., 1993; Georgakakos et al., 1996; Bell and Moore, 1998; Vieux and  
6 Bedient, 1998; Winchell et al., 1998; Sempere-Torres et al., 1999; Borga et al.,  
7 2000; Ogden et al., 2000). The use of radar is especially useful in catchments  
8 containing coarse rain gauge networks, producing process-realistic distributed  
9 runoff simulations (e.g. Michaud and Sorooshian, 1994; Lange et al., 1999; Woods  
10 et al., 2000). Radar rainfall estimation is, nevertheless, also subject to a range of  
11 errors caused by factors that include instrumentation issues (e.g. calibration,  
12 measurement noise) and complexity and variability in the relationship occurring  
13 between recorded measurements and precipitation parameters (Austin, 1987; Joss  
14 and Lee, 1995; Andrieu et al., 1997; Borga et al., 2002). These different sources of  
15 error act to compound the radar rainfall uncertainty and can have a significant  
16 impact on the accuracy of rainfall-runoff forecasting (Borga, 2002).

17  
18  
19  
20  
21  
22  
23  
24  
25 The argument that data-driven modellers should take greater account of  
26 hydrological processes representation, has resulted in a number of recent studies  
27 that have attempted to adapt standard data-driven modelling approaches, so that a  
28 degree of relevant knowledge about hydrological processes and data uncertainty is  
29 better represented in the model structure (e.g. Chen and Adams, 2006; Corzo and  
30 Solomatine, 2007; Corzo et al., 2009; Song et al., in press). Nonetheless, the  
31 majority of data-driven rainfall-runoff models continue to emphasise temporal  
32 variation in hydrological processes, and largely ignore the impact of spatial variation  
33 in the model inputs. The result is a dominance of spatially-lumped data-driven  
34 studies, and this is especially true in the case of rainfall-runoff models (e.g. Nayak  
35 et al., 2005; Chiang and Chang, 2009; Wu and Chau, 2011; De Vos, 2012). Despite  
36 its obvious potential as a means by which spatial variation can be captured and  
37 incorporated, few data-driven modelling studies have attempted to use  
38 raster-based radar rainfall (e.g. Teschl and Randeu, 2006; Teschl et al., 2009;  
39 Chaipimonplin et al., 2010) or satellite rainfall (e.g. Akhtar et al., 2009) inputs. One  
40 reason for this is that each grid cell ultimately represents a separate potential input  
41 for a data-driven model, such that utilising raster data in its raw form is impractical  
42 and inefficient. Instead, a trade-off is required in which an optimised  
43 spatio-temporal lumping strategy is applied to any continuous rainfall data;  
44 resulting in a semi-distributed data-driven modelling framework.

The aim of this paper is to enhance our understanding of the extent to which greater  
incorporation of fundamental hydrological process knowledge, can deliver superior  
forecast performance for complex hydrological phenomenon. To this end, our core

1  
2  
3 objective is to exemplify how different levels of semi-distribution, applied to  
4 continuous radar rainfall data inputs, operating in a data-driven rainfall-runoff  
5 modelling framework, affect the performance of multi-step-ahead reservoir inflow  
6 forecasts in Taiwan. Taiwan represents an excellent study site because it  
7 experiences conditions of extreme spatial and temporal rainfall heterogeneity  
8 associated with typhoon events. In this paper the Adaptive Network-based Fuzzy  
9 Inference System (ANFIS: Jang, 1993; Jang et al., 1997) is used to forecast  
10 reservoir inflow for a range of different forecasting horizons. We develop a set of  
11 models based on different levels of radar rainfall spatial disaggregation, from which  
12 a model with the preferred level of input distribution is identified. Results are  
13 compared against counterpart solutions developed on point-based rainfall inputs  
14 from traditional rain gauges. Justification of the application of a complex, non-linear  
15 data-driven modelling algorithm is made by means of multiple linear regression  
16 benchmarks.

## 25 2. RESERVOIR INFLOW FORECASTING IN TAIWAN

27  
28 Taiwan is situated within the main track of western North Pacific typhoons. In an  
29 average year, Taiwan experiences between four and five typhoons that occur  
30 between June and November. There is little consistency in the direction of the  
31 typhoon paths (Figure 1: Taiwan Central Weather Bureau, pers. comm.), primarily  
32 due to Taiwan being located at a turning point on the track for most typhoons  
33 occurring in the Western North Pacific–East Asian region (Camargo et al., 2007; Chu  
34 et al., 2012); but also, potentially, on account of long term trends or low-frequency,  
35 large scale atmospheric shifts relating to climate change (Kao et al., 2012; Lee et al.,  
36 in press). Significant variation exists in the individual strength of a particular  
37 typhoon and the speed and direction of motion of its track. These factors control the  
38 intensity, spatial distribution and total volume of rainfall it delivers (Lee et al., 2006;  
39 Pan et al., 2012). Thus typhoons are characterised by substantial spatio-temporal  
40 heterogeneity, which means that the spatial and temporal distribution of  
41 typhoon-associated heavy rainfall will be highly complex and differ from event to  
42 event. The impact of such rainfall, moreover, will in all likelihood be exacerbated as  
43 a result of climate change which is expected to deliver increased typhoon  
44 frequencies (Lee and You, 2011).

53  
54 Taiwan's topography is characterized by a mountainous north-south trending central  
55 belt, with steep-slopes and short, fast flowing rivers. Several upland rivers have  
56 been dammed to form reservoirs, which can be inundated within a few hours as a  
57

1  
2  
3 result of extreme runoff events linked to the passage of typhoons (Chang et al.,  
4 2002). The inflow to these reservoirs is mainly the result of localised rainfall (Yu et  
5 al., 2006), with only limited contributions from groundwater; thus rainfall-runoff  
6 models represent an important means by which streamflow is predicted (e.g. Vieux  
7 et al., 2003; Yu et al., 2004; Wu et al., 2007).

8  
9  
10  
11 During a typhoon, important decisions about the timing and amount of any required  
12 reservoir releases must be made within a matter of hours by the controlling agency.  
13 Most reservoir operations are guided by simultaneously balancing flood control and  
14 water supply. In general, reservoir operations for flood control can be separated into  
15 three different stages (Hsu and Wei, 2007): (1) stage prior to flood arrival, in which  
16 water releases are designed to reserve sufficient reservoir capacity for the  
17 upcoming flood; (2) stage preceding peak inflow, in which floodwater releases are  
18 applied for disaster mitigation; and (3) stage after peak inflow, in which reservoir  
19 releases are used to regulate the storage at the end of each flood, for future water  
20 purposes. The correct operation of these stages involves the use of look-up tables,  
21 which provide rules for the standardised release of water during typhoon periods.  
22 These tables are graded by total forecasted rainfall, observed storage level, and  
23 reservoir inflow during flood periods.  
24  
25  
26  
27  
28  
29  
30

31 The implication of current practice in reservoir decision-making procedures is that  
32 for operational management purposes an advanced knowledge of flood peak  
33 magnitude and timing is required, empowering the controller to select an  
34 appropriate course of action. Moreover, armed with such information, it becomes  
35 possible for the controlling agency to deliver an appropriate set of statutory  
36 warnings to mass/local media, pertinent institutions and downstream residents  
37 several hours in advance of any proposed water releases. Thus, in balancing the  
38 reservoir, timing is a critical factor and a rainfall-runoff model that can deliver  
39 accurate, real-time predictions for forecasting horizons that exceed three or more  
40 hours ahead of present is called for. This requires the best possible short-term  
41 multi-step-ahead reservoir inflow forecasting model; one that will eventually form  
42 an integrated and trustworthy component of the reservoir management and  
43 operational decision-making process.  
44  
45  
46  
47  
48  
49  
50

### 51 **2.1. Short-term, multi-step ahead reservoir inflow forecasting**

52  
53  
54 Generating short period ahead forecasts of reservoir inflow by means of standard,  
55 spatially-distributed physical models, applied in real time (e.g. Wu et al., 2007; Wu  
56 et al., 2008), is problematic because the generation of ahead-of-time forecasts  
57  
58  
59  
60

1  
2  
3 necessitates the use of uncertain, forecasted inputs in a modelling framework that is  
4 designed to be instantaneous and continuously-updating. Moreover, the complex  
5 data needs and parameterisation requirements of physically-based models make  
6 their application difficult in many of Taiwan's reservoirs that are fed from remote,  
7 mountainous, catchments (Wu et al., 2008). An alternative approach is  
8 multi-step-ahead forecasting in which the general relationship between lagged and  
9 instantaneous inputs, and an inflow record shifted progressively forward in time, is  
10 quantified and reapplied (e.g. Chang et al., 2007; Toth and Brath, 2007; Yonaba et  
11 al., 2010). In this context, a forecast is generated for multiple periods (or steps)  
12 ahead using a mix of past records and real-time measurements. Data driven models  
13 are particularly good at multi-step-ahead forecasting due to their ability to  
14 determine the optimal relationships that relate inputs to outputs; albeit with a  
15 reduction in their predictive capabilities over longer forecast horizons (Campolo et  
16 al., 1999; Babovic and Keijzer, 2002; Nayak et al., 2005; Xu and Li, 2002; Dawson  
17 et al., 2006). They are also flexible enough to enable the development of models  
18 that accommodate spatial and temporal heterogeneity in the model inputs (Lorrai  
19 and Sechi, 1995; Rajurkar et al., 2002).

20  
21  
22 From the range of different data-driven rainfall-runoff modelling and streamflow  
23 forecasting investigations that have been published, ANFIS has emerged as a  
24 particularly promising method of dealing with complex time series data sets,  
25 following its first reported application to hydrological modelling problems by  
26 Gautam and Holz (2001) e.g. Keskin et al. (2006); Bae et al. (2007); Firat and  
27 Güngör (2008); Pramanik and Panda (2009); Talei et al. (2010); Nguyen and Chau  
28 (2012); Ghalkhani et al. (in press). Of particular importance for this study is  
29 recently-reported success in its ability to discover the optimal relationship between  
30 current and antecedent rainfall and reservoir inflow inputs and multi-step-ahead  
31 reservoir inflow outputs (El-Shafie, 2007; Jothiprakash and Magar, 2012). However,  
32 any implementation of a distributed, ANFIS modelling framework is potentially  
33 problematic, because the use of large numbers of distributed inputs is likely to result  
34 in a grossly inefficient solution. In addition, local noise (both spatial and temporal)  
35 in the rainfall data which is used to drive such models risks masking the broader  
36 hydrological signal that one wishes to capture (Lin and Chen, 2005; Dark and Bram,  
37 2007). Therefore, in developing a semi-distributed multi-step-ahead ANFIS  
38 rainfall-runoff model, it is essential that some preferred level of input spatial  
39 aggregation is identified which both maximises the strength of the hydrological  
40 signal that can be modelled, and minimises noise due to input uncertainty and  
41 model inefficiency.

### 3. STUDY AREA AND DATASETS

The Shihmen Reservoir (Figure 2) was built in 1964 and is one of the largest and most important reservoirs in Taiwan. It has been the focus of a number of previous studies that have modelled the catchment hydrology for the purpose of inflow prediction. Recent examples include the development and application a physically-based distributed parameter model (Wu et al., 2008) and two different sorts of neural network model (Chen and Chang, 2009; Lin et al., 2009a). Located on the upper reaches of the Tahan River, it has an upstream contributing area of 763.4 km<sup>2</sup>, ranging in elevation from 157 m to 3514 m, with average slope angles of about 30 degrees. It has an effective capacity of 219 million cubic metres and is designed for multiple purposes including water supply for irrigation, industrial and domestic uses, flood control, and hydropower generation. The reservoir is currently managed by the Water Resources Agency which stipulates rules for operational flood control (Water Resources Agency, 1984).

The rainfall and inflow datasets used in this study were provided by the Water Resources Agency and Central Weather Bureau of Taiwan and used as supplied. In common with standard practice in data-driven modelling studies, additional preprocessing was not performed (Abrahart et al., 2010). The use of third-party data inhibited meaningful adjustment or correction of observed records for original measurement error, and detailed information on data collection practices or data quality control procedures were not made available. Similarly, rain gauge point-based rainfall records and radar grid-based rainfall records were used as supplied, without adjustments for elevation. The reservoir inflow series comprised 445 hourly observations for eight typhoon events, occurring between 2007 and 2009, in which peak inflow per event across the series ranged from a maximum of 5300 m<sup>3</sup> s<sup>-1</sup> for KROSA (Event 2: SSHS Category 4 Super Typhoon) to a minimum of 203 m<sup>3</sup> s<sup>-1</sup> for KALMAEGI (Event 3: SSHS Category 2 Moderate Typhoon that delivered very little rainfall in our catchment) (Table 1). Figure 3 shows the reservoir inflow records depicted as a continuous series for the eight typhoons, highlighting substantial differences in the duration and magnitude of each individual storm event. Two different sorts of rainfall data were available for the eight typhoon events: hourly rainfall data for 12 gauges distributed across the catchment (Figure 2); and a corresponding radar rainfall data set produced from QPESUMS (Quantitative Precipitation Estimation and Segregation Using Multiple Sensors: <http://www.nssl.noaa.gov/projects/qpesums/>). Full particulars are provided in

1  
2  
3 Table 2. The radar rainfall data had a temporal resolution of 10 minutes and a spatial  
4 resolution of 1.25 km. This raster data set had already been calibrated, using  
5 ground observations, by the Central Weather Bureau, Taiwan. The 10-minute  
6 precipitation map was temporally accumulated into an hourly sequence,  
7 corresponding to our hourly rain gauge data and hourly reservoir inflow series. The  
8 study also utilised a 40 m resolution digital elevation model (DEM) provided by the  
9 National Land Surveying and Mapping Center, Taiwan for sub-catchment  
10 segmentation analysis. The DEM was constructed from stereo-pair imagery in 1995  
11 by the Aerial Survey Office, Taiwan and has a vertical accuracy of between 2.5 m  
12 and 5.0 m.

#### 18 19 **4. METHODOLOGY**

20  
21  
22 Within the context of the existing rules that govern reservoir releases in Taiwan, we  
23 develop modelling procedures that are capable of generating reliable estimates of  
24 peak reservoir inflow magnitude and timing over intervals that exceed the statutory  
25 minimum requirement. It is important to note that we do not exemplify the  
26 application of the operational procedures or seek to improve or change them.  
27 Instead, we focus on the development of a model that can deliver improved forecast  
28 information, which can subsequently be used to support better application of the  
29 existing operational rule sets. The purpose of the modelling exercise is thus to  
30 generate the best performing real-time, instantaneous multi-hour step-ahead  
31 forecast of reservoir inflow for the reservoir in question. From this, the predicted  
32 water accumulation within the reservoir can be continuously updated, and decisions  
33 about the timing of any required reservoir release(s) can be made in advance of  
34 their occurrence. To this end, the model predictions are not constrained to peak  
35 inflows, but extend across the entire hydrologic response of the catchment.  
36  
37  
38  
39  
40  
41  
42

43 Three stages of model development (Stages 1-3), which are the main focus of this  
44 paper, are required before a real-time multi-step ahead model can be applied in an  
45 operational capacity (Stage 4):  
46  
47

- 48 1. The collation and pre-processing of available rainfall and discharge records  
49 for the catchment (see Section 3.1);
- 50 2. The construction of numerous multi-step-ahead data-driven models (listed  
51 below) using a range of different inputs and different levels of spatial  
52 aggregation (see Section 3.2);
- 53 3. The identification of a model structure that is best able to deliver step-ahead  
54 inflow forecasts over increasingly large time steps (according to both level of  
55  
56  
57  
58  
59  
60

- 1  
2  
3 spatial aggregation employed and other inputs) (see Section 3.3);  
4 4. The re-application of our preferred model structure (identified at Stage 3).  
5  
6

7 Inflow into the Shihmen reservoir was modelled for forecast horizons of  
8  $Q_{t+1}, Q_{t+2}, \dots, Q_{t+5}$  hours ahead using six modelling approaches of increasing  
9 complexity (Table 3):  
10

11  
12 Model A: A simple two-input model based solely on the reservoir inflow record.  
13 Inputs comprised inflow at time  $t$ , and the change (difference) in  
14 inflow between  $Q_t$  and  $Q_{t-1}$ , hereafter termed  $\Delta Q$ . This model  
15 represents the minimum complexity solution against which models  
16 using either rainfall or radar as additional inputs can be compared.  
17  
18

19  
20 Model B: A rainfall-runoff model with inputs comprising 12 lagged, point-based  
21 rain gauge records,  $Q_t$  and  $\Delta Q$ . This model represents a standard  
22 configuration for including rain gauge inputs in data-driven  
23 rainfall-runoff models (e.g. Deo and Thirumalaiah, 2000).  
24  
25

26  
27 Model C: A lumped rainfall-runoff model with inputs comprising lagged total  
28 rainfall, derived from radar data and spatially averaged across the  
29 entire catchment,  $Q_t$  and  $\Delta Q$ . This model represents the simplest  
30 application of spatial lumping, and provides a baseline against which  
31 the additional performance of semi-distributed modelling  
32 configurations can be assessed.  
33  
34

35  
36 Models D-F: A suite of semi-distributed rainfall-runoff models (ranging from 4 to  
37 12 sub catchments), with inputs comprising lagged total rainfall,  
38 derived from radar data and spatially averaged across each sub  
39 catchment,  $Q_t$  and  $\Delta Q$ . This sequential partitioning provides specific  
40 insight into the relationship between different levels of spatial  
41 aggregation and data-driven model prediction accuracy.  
42  
43  
44  
45  
46  
47

48  
49 In accordance with past recommendations (Abrahart and See, 2007; Mount and  
50 Abrahart, 2011b), each ANFIS instantiation of the four approaches was also  
51 benchmarked against a set of counterpart linear regression models. In this way the  
52 additional benefit of employing complex, ANFIS-based modelling could be  
53 determined. In contrast to several earlier ANFIS papers, we do not provide  
54 additional neural network model benchmarks; for example, by means of developing  
55 and reporting a standard counterpart backpropagation-of-error trained feedforward  
56  
57  
58  
59  
60

neural network (FFNN: Abrahart and See, 2000). Following Chang and Chang (2006), who also only applied an ANFIS solution to their successful data-driven modelling of reservoir water level at this location, we direct our focus away from algorithm comparison for reservoir inflow forecasting as many other papers have already addressed such issues, (e.g. Chang et al., 2007; Lin et al., 2009b; Karimi-Googhari and Lee, 2011). Instead we focus on examining the benefits that result from undertaking data-driven rainfall-runoff modelling in a spatially-disaggregated manner. Two further justifications for our decision to omit the additional reporting of simpler-structured FFNNs should also be documented. First, where ANFIS and FFNN model counterparts have previously been compared in the context of step-ahead hydrological forecasting studies, the performance of ANFIS solutions is consistently equal to, or slightly in excess of its simpler FFNN model counterparts (e.g. Chau et al., 2005; Nayak et al., 2005; Chen et al., 2006; Mukerji et al., 2009; Lohani et al., 2012). There is no reason to presume that the findings of our current study would be significantly different from that of previous work. Second, delivering routine comparisons, in which alternative categories of neural algorithm are directly matched one against another, can at best deliver only 'incremental refinement' of existing expertise and/or scientific knowledge (Abrahart et al., 2012); potentially offering only marginal improvement in accuracy, low intellectual reward and no step-change in hydrological modelling understanding or application development.

#### **4.1. Derivation of model inputs**

##### **4.1.1. Inflow Inputs**

Numerous modelling studies have shown that, over short forecast horizons, simple one-step-ahead autoregressive models will provide good predictions of inflow over a broad range of different hydrological settings (Niedzielski, 2007). However, one-step-ahead models can suffer from local preferencing; where the predictive power of all lagged inputs is minimised in favour of the last observed record, if the latter is included as an input (Abrahart et al., 2007). The upshot of this for data-driven modelling is that one-step-ahead solutions can easily become trapped into producing a minimally-modified autoregressive single-input single-output model. To reduce the likelihood of this occurring, the lagged inflow input in each of our models is modified into a standardised rate of change:  $\Delta Q$ . This increases the dimensionality of our drivers and, simultaneously, ensures that both positive and negative values are provided. This deviation from standard data-driven modelling practice is intended to reduce the marginalisation of lagged data during model

1  
2  
3 training and offer greater potential for non-current inputs to influence the model  
4 output. Moreover, if the dominant impact of inflow is countered, the significance of  
5 rainfall records should be accentuated and might logically be expected to deliver a  
6 reduction in timing error.  
7  
8  
9

#### 10 **4.1.2. Rain Gauge Inputs**

11  
12 In contrast to the simple inflow model, the use of rain gauge inputs requires  
13 consideration of the spatial distribution of measurement records, and of variable  
14 travel times occurring between the rainfall recorded at the gauge and the inflow  
15 response at the point of reservoir inflow forecast. Therefore, the challenge is to  
16 identify the most representative travel time for each gauge. In this study, we  
17 examine all travel times from 0 to 10 hours by means of correlation analysis:  
18 standard practice in data-driven hydrological modelling (Maier and Dandy, 2000;  
19 Maier et al., 2010). However, variability in the typhoon tracks presents additional  
20 complexity which will result in inconsistent lag response times between each gauge  
21 and the reservoir inflow during different events. Thus, a three-stage combination  
22 and selection process was adopted:  
23  
24  
25  
26  
27  
28

- 29  
30 1. For each of the 12 gauges, compute a correlation coefficient for each of  
31 8 individual typhoon events at each of the 11 reservoir inflow travel  
32 times (i.e. calculate 1056 individual correlation coefficients);  
33
- 34 2. For each of the 11 travel times at each of the 12 gauges, compute a  
35 mean correlation coefficient that spans 8 typhoon events (i.e. convert  
36 1056 individual correlation coefficients into 132 mean correlation  
37 coefficients).  
38
- 39 3. For each gauge, select the travel time to be used based on the  
40 maximum mean correlation coefficient.  
41  
42

43  
44 The results of Steps 2 and 3 are presented in Table 4.  
45

#### 46 **4.1.3. Radar Inputs**

47  
48 The use of radar data allows us to replace spatially-discrete rain gauge modelling  
49 inputs with spatially-continuous representations. In total, 434 grid cells comprise  
50 the radar data set for this catchment. In order to prevent the development of an  
51 excessively complex solution, spatial lumping was performed by aggregating radar  
52 values to increasing numbers of hydrological sub-units. The original catchment was  
53 partitioned into sub-catchment polygons, based on different levels of stream  
54 segmentation, according to the DEM method of Jensen and Domingue (1988) - as  
55  
56  
57  
58  
59  
60

1  
2  
3 implemented in Arc Hydro (Maidment, 2002). Flow accumulation thresholds of  
4  $T=100$ ;  $T=30$  and  $T=25$  resulted in 4, 8 and 12 sub-catchment discretisations; with  
5 12 being equal to the number of rain gauges in Model B. Radar data values were  
6 subsequently assigned to the full catchment and each of its sub-catchment polygons  
7 according to whether or not the centroid of a particular radar cell fell inside its  
8 boundary. The total hourly rainfall for each polygon was thereafter calculated by  
9 means of summation, resulting in a set of instantaneous rainfall inputs at four  
10 different levels of spatial lumping [1 (Model C), 4 (Model D), 8 (Model E) and 12  
11 (Model F)]. Table 5 contains descriptive statistics of the aggregated radar rainfall  
12 data for each individual polygon.  
13  
14  
15  
16  
17  
18

19 For hourly radar rainfall, correlation analysis was performed on the aggregated  
20 radar rainfall data for each polygon in a manner identical to that for gauged rainfall,  
21 by again examining travel times that ranged from 0 to 10 hours. Mean correlation  
22 coefficients were calculated across the 8 typhoon events, with the representative  
23 travel time for each polygon selected on the basis of the maximum mean coefficient.  
24 The travel times assigned to each polygon are presented in Figure 4. At 4 and 8 sub  
25 catchments, the spatial assignment of travel times appears rational, with travel time  
26 increasing with distance from the reservoir inflow. At 12 sub catchments, the spatial  
27 pattern is less rational, with instances of upstream sub catchments being assigned  
28 quicker travel times than some of their downstream neighbours.  
29  
30  
31  
32  
33  
34

#### 35 **4.2. Data-driven Modelling**

36  
37 ANFIS models were developed in MATLAB for our five forecasting horizons  
38 ( $Q_{t+1}, Q_{t+2}, \dots, Q_{t+5}$ ) using each of the six approaches (A-F), resulting in 30 final models.  
39 The Fuzzy Logic Toolbox *genfis3* function was used to determine the structure of  
40 each fuzzy information system, by the application of fuzzy c-means. The number of  
41 clusters required by the c-means algorithm was provided by the user and, in turn,  
42 this parameter set the number of membership functions per input and number of  
43 output rules per model so that in each case they equalled the number of clusters  
44 used. For each of these 30 models, a multiple linear regression (MLR) counterpart  
45 was also developed.  
46  
47  
48  
49  
50  
51

52 ANFIS is a five-layer feedforward network, applying a neural network learning  
53 algorithm and fuzzy reasoning to map input predictor variables onto an output  
54 predictand space. The basic architecture is described in detail in numerous other  
55 hydrological modelling papers and, as such, need not be repeated in our paper (e.g.  
56 Chang et al., 2005). The optimal structure for each ANFIS model used in our  
57  
58  
59  
60

experiments was determined by heuristic search; with the best-performing configuration selected according to its ability to minimise RMSE. In common with other default settings of the *genfis3* function, a Gaussian fuzzy membership input function was applied in all cases, necessitating subsequent optimisation of mean and standard deviation parameters. The output membership function was by default linear. The number of clusters (number of membership functions per input/ number of output rules per model) searched was varied from 2 (minimum) to 14 via manipulation of the *cluster\_n* parameter in *genfis3*. The modelling records were divided into three sub-sets: Events 1-5 formed the training dataset; Events 6 and 7 formed the cross-validation dataset; Event 8 formed the testing dataset. The largest and smallest events were included in the training dataset, such that the need for extrapolation beyond the range of the training dataset was avoided. Early stopping (Coullibaly et al., 2000; Giustolisi and Laucelli, 2005) was applied to prevent over-fitting. The ANFIS default hybrid learning algorithm was employed to identify model parameters: delivering a powerful combination of least-squares fitting and backpropagation gradient descent methods. The optimal configuration and stopping point for each of our 30 preferred models is shown in Table 6.

#### 4.3. Evaluation metrics

The performance of each model was evaluated and compared using five different metrics: correlation coefficient (CC: Equation 1), root mean square error (RMSE: Equation 2), mean square error (MSE: Equation 3), coefficient of efficiency (CE: Equation 4) and skill score (SS: Equation 5). Further particulars on the first four metrics can be found in Dawson et al. (2007). SS is a measure of improvement in RMSE: using a reference model as benchmark, in which a positive score indicates superior performance of a model over that benchmark model. These indices served as criteria for model selection: to identify the preferred input combination and, consequently, an optimal level of spatio-temporal aggregation for the radar rainfall modelling scenarios under test.

$$CC = \frac{\sum_{t=1}^N [Q_{pre}(t) - \bar{Q}_{pre}] [Q_{obs}(t) - \bar{Q}_{obs}]}{\sqrt{\sum_{t=1}^N [Q_{pre}(t) - \bar{Q}_{pre}]^2} \sqrt{\sum_{t=1}^N [Q_{obs}(t) - \bar{Q}_{obs}]^2}} \quad \text{Equation 1}$$

$$RMSE = \sqrt{\frac{\sum_{t=1}^N [Q_{pre}(t) - Q_{obs}(t)]^2}{N}} \quad \text{Equation 2}$$

$$\text{MAE} = \frac{\sum_{t=1}^N |Q_{pre}(t) - Q_{obs}(t)|}{N} \quad \text{Equation 3}$$

$$\text{CE} = 1 - \frac{\sum_{t=1}^N [Q_{obs}(t) - Q_{pre}(t)]^2}{\sum_{t=1}^N [Q_{obs}(t) - \bar{Q}_{obs}]^2} \quad \text{Equation 4}$$

$$\text{SS} = \frac{E_m - E_n}{E_m} \times 100\% \quad \text{Equation 5}$$

where  $N$  is the number of observations,  $Q_{pre}(t)$  is the predicted inflow at time  $t$ ,  $Q_{obs}(t)$  is the observed inflow at time  $t$ ,  $\bar{Q}_{pre}$  and  $\bar{Q}_{obs}$  are the mean value of predicted and observed inflow, respectively.  $E_m$  is the RMSE of a reference model, in this study Model A.  $E_n$  is the RMSE of the model compared.

## 5. RESULTS

Test data set results for all 30 ANFIS models are presented in Figures 5 and 6. For the one and two-hour ahead forecasting horizons ( $Q_{t+1}, Q_{t+2}$ ), the metrics indicate similar, high levels of performance for all models. This clearly reflects the limited challenge involved in very short-term reservoir inflow forecasting for the Shihmen catchment. However, as the forecasting horizon is increased, clear differences in the performance of individual models become apparent.

For forecasting horizons  $Q_{t+3}$  to  $Q_{t+5}$ , Models A and B deliver similarly poor performance. This implies that the addition of spatially-distributed, point-based data provides little advantage over a simple lagged inflow model. Presumably, this is because the degree of useful spatial information that is encoded within the model inputs is highly limited. Indeed, the inclusion of continuous spatial data, even as a wholly lumped input (Model C) is shown to result in improved performance at forecasting horizons greater than  $Q_{t+2}$ . This suggests that, even without additional spatial discretisation, continuous rainfall data should be used in preference to

1  
2  
3 point-based, gauged inputs.  
4  
5

6 Further improvements in model performance are observed when the catchment is  
7 discretised into four separate sub-catchments (Model D). Moreover, the  
8 performance advantage over all other models becomes consistently greater as the  
9 forecasting horizon is increased towards  $Q_{t+5}$ . Of interest is the fact that this pattern  
10 of improvement is not carried through to models E and F. Indeed, the use of 8 and  
11 12 sub-catchments results in models that, in most cases, perform worse than their  
12 simple lumped catchment counterpart (Model C). It demonstrates that there are  
13 clear limits to the amount of discretisation that should be applied in this case. This  
14 arises from the need to generalise highly complex, spatio-temporal patterns of  
15 typhoon events and their relationship to inflow, something which would require the  
16 use of a well-parameterised, spatially and temporally-distributed, physically-based  
17 model to properly forecast. Instead, data-driven modellers must adopt a more  
18 pragmatic position in which the relationships between data sets must be simplified  
19 through both temporal and spatial lumping: both of which are applied in this study.  
20  
21  
22  
23  
24  
25

26  
27 Figure 7 compares observed and predicted inflow series for Model B and Model D,  
28 calculated on the testing data (typhoon Jangmi) across different lead times. The  
29 plots confirm that predicted values for Model D are much closer to the observed  
30 values. It is also worth noting that for  $Q_{t+5}$ , the substantial timing-error  
31 displacement of predicted peak inflow decreased from 6 hours for Model B to 3 hours  
32 for Model D. This indicates that the spatio-temporal optimisation of radar rainfall is  
33 not only capable of increasing the overall performance of models across the five  
34 metrics that were applied but also reduces the frequently overlooked problem of a  
35 spurious lagged time shift component appearing in data-driven model outputs (De  
36 Vos and Rientjes, 2005; Abrahart et al., 2007).  
37  
38  
39  
40  
41

42  
43 Figures 8 and 9 compare non-linear (ANFIS) and linear (MLR) rainfall-runoff  
44 reservoir inflow forecasting counterparts. RMSE (Figure 8) and CE (Figure 9)  
45 performance indices showed that ANFIS models were almost invariably superior to  
46 MLR models, and always so over longer forecast horizons. These results confirm the  
47 near-linear nature of one-step-ahead forecasting and that increased non-linearity  
48 occurs over longer forecasting horizons. It also confirms the need to develop  
49 non-linear modelling solutions for providing multi-step-ahead forecast reservoir  
50 inflow related to typhoon events in Taiwan.

## 56 **6. DISCUSSION AND WIDER IMPLICATIONS**

57  
58  
59  
60

1  
2  
3 The novel contribution of this paper is its exploration of how the inclusion of  
4 spatial-distribution in a data-driven rainfall-runoff model enhances its predictive  
5 performance by better capturing the spatial and temporal heterogeneity of typhoon  
6 rainfall events. Our results reveal clear improvements associated with the adoption  
7 of a semi-distributed data-driven modelling framework; offering potential benefits  
8 for similar studies conducted under differing conditions, since catchment  
9 sub-partitioning is easily reproduced. This finding conforms to the widely-held  
10 viewpoint that errors associated with the estimation of rainfall intensity from  
11 lumped models are very likely to limit a model's ability to predict runoff accurately,  
12 and that this will be a particular problem where high-intensity, convective rainfall is  
13 known to be the key driver of runoff (Dawdy and Bergman, 1969; Wilson et al.,  
14 1979). Such results also support the notion that there may be an optimal level of  
15 discretisation beyond which anticipated performance benefit decreases due to local  
16 noise and uncertainty in the rainfall data masking the broader hydrological signal for  
17 a catchment (Lin and Chen, 2005; Dark and Bram, 2007). Thus, it is important to  
18 caution against the assumption that data-driven rainfall-runoff model accuracy will  
19 necessarily be improved by simply increasing the degree of spatial distribution  
20 employed. It is interesting to note that recommendations of the Distributed Model  
21 Intercomparison Project also caution against such an assumption (Reed et al.,  
22 2004). That project utilised gridded radar rainfall data provided as hourly  
23 accumulations, and showed that lumped models can still outperform distributed  
24 models. Further, it revealed that individual catchment characteristics are central to  
25 the performance advantages of lumped or distributed models. Indeed, in situations  
26 where improved results obtained from distributed models driven by radar rainfall  
27 input are reported, they are often associated with isolated case studies rather than  
28 routine operational predictions. Consequently, the general benefits of incorporating  
29 spatial distribution, and the importance of the different factors that affect it, remain  
30 a debated topic amongst physically-based modellers (Tetzlaff and Uhlenbrook,  
31 2005; Berne & Krajewski, 2012).

32  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46 Our paper also makes a significant contribution by providing some beneficial  
47 insights regarding the underutilised advantages of adopting radar data as an input  
48 into data-driven rainfall-runoff models, rather than the more established use of  
49 point-based rain gauge data. Whilst a large number of studies have compared the  
50 use of rain gauge and radar data (e.g. Briggs and Atkinson, 2011) and the impact of  
51 radar rainfall error and uncertainty on water resources modelling (e.g. Hossain et  
52 al., 2005; Habib et al., 2008; Gourley et al., 2011; He et al., 2011; Schrötera et al.,  
53 2011), none have considered the issues from a specifically data-driven modelling  
54 perspective. The reported method represents a significant advance over the

1  
2  
3 previous use of lumped mean areal inputs (Lorrai and Sechi, 1995), or distributed  
4 point-based rainfall samples (Campolo et al., 1999; Dawson et al., 2006), given that  
5 such past approaches possess no explicit physical or operational underpinnings. It is  
6 also a physical and structural enrichment of previous data-driven radar rainfall  
7 modelling procedures applied by Teschl and Randeu (2006), and of the spatial  
8 clustering arguments of Rajurkar et al. (2002) and Lauzon et al. (2006), which are  
9 modified by the adoption of physically-meaningful sub-catchment boundaries,  
10 developed using drainage network analysis of a digital elevation model. To this  
11 extent, a basic level of meaningful, hydrological process knowledge is incorporated  
12 into the modelling framework.  
13  
14  
15  
16  
17

18  
19 Strong parallels exist between the ideas developed in this work and those  
20 associated with hybrid modelling solutions (Perez, 2009). Hybridisation in most  
21 cases involves the development of a mixed combination of two or more different  
22 types of model in which each individual model fulfils a particular role in some larger  
23 scheme. Data-driven solutions, for example, can be externally coupled to a  
24 conventional model (standalone solution) or embedded within it (modular  
25 component). In a similar manner it is possible to exploit the predictive capabilities of  
26 data-driven models within a semi-distributed model structure, drawing upon the  
27 physical rationality of such approaches, which better reflects the nature of the  
28 hydrological phenomena that is required to be modelled. Hybrid solutions are  
29 usually characterised by relatively complex, modular solutions in which different  
30 data-driven models are developed for one or more individual components of the  
31 catchment being modelled (e.g. a different model for each sub-catchment, or for  
32 each hydrological process operating within the catchment), and subsequently  
33 combined (e.g. Corzo et al., 2009; Huo et al., 2012). By contrast, our study adopts  
34 a simpler approach involving the use of semi-distributed model *inputs* as opposed to  
35 enforcing spatial distribution in the model structure itself. In this way the predictive  
36 benefits that result from the use of different levels of semi-distribution in the model  
37 inputs are tested: an important requirement when one or more model inputs are  
38 derived from a spatially-continuous data set. The resultant model is, arguably, a  
39 simplified hybrid solution that achieves an optimal degree of generalisation of the  
40 spatio-temporal variability in typhoon rainfall-runoff processes, whilst avoiding an  
41 overly-complex, fully-distributed model structure that would require inputs and  
42 parameters that are difficult to obtain.  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53

54  
55 As with many scientific disciplines, a range of methodological approaches and  
56 associated techniques for tackling hydrological problems have emerged, that are  
57 founded on different conceptual and philosophical schools of thought about how  
58  
59  
60

hydrological processes should be represented and captured within a set of relevant models (Wainwright and Mulligan, 2004). Modelling ranges from highly inductive, physically-based, to highly deductive, empirical and data-driven, and clearly different sorts of model are needed to serve a number of different purposes. Many of the approaches associated with particular schools have been developed exclusively, with relatively limited transfer and incorporation of specific techniques and ideas occurring across the wider disciplinary and scientific community. This paper exemplifies how the incorporation of the most basic physical concepts in hydrology may be integrated into a data-driven methodology so that the physical rationality of the data-driven product is a core element of the resultant model. In so doing, it supports the notion that hydrologists, irrespective of their conceptual background or philosophical stance, should where possible, seek to incorporate the ideas and knowledge that is best suited to the nature of the problem that they are trying to solve. These may derive from other parts of the discipline or beyond, and may result in models that are substantially different from those that are accepted practice within a particular school of thought. We accordingly encourage data-driven modellers to engage more fully with physical concepts in hydrology, and physical modellers to consider how data-driven techniques may be of benefit to them.

## 7. CONCLUSIONS

Four key points emerge from this study:

1. Continuous rainfall data appears to offer performance advantages over discrete, point-based spatial data for reservoir inflow forecasting in Taiwan.
2. Further performance advantages can be achieved by using a semi-distributed modelling framework, but there are limits to the number of catchment sub-units that should be used.
3. The spatio-temporal complexity of typhoon rainfall requires a substantial amount of spatial and temporal generalisation in order to build an effective data-driven rainfall-runoff model.
4. The operational requirement for a minimum 3-hour warning of reservoir release requires the availability of a model that performs well over lead times in excess of three hours. This study indicates that data-driven models are of use in this regard, and that their value is maximised when appropriately-distributed, continuous radar rainfall data is used.

60

This study has highlighted the importance of the spatial dimension in data-driven, rainfall-runoff modelling. To date, this factor has received little attention by researchers in the field. There is, therefore, a clear need for additional research into the effects of spatio-temporal generalisation on data-driven models, applied in different hydrologic and physiographic contexts. This study has demonstrated the specific capability of ANFIS, selected as a typical data-driven modelling tool. Whilst further potential improvements in performance accuracy could probably be obtained from the application of other data-driven algorithms, it is unlikely that such gains would be anything other than marginal, given that previously-published hydrological comparisons of ANFIS and other data-driven algorithms demonstrate broadly similar outcomes (e.g. Chen et al., 2006).

Table 1 Typhoon dataset

Event	Name	SSHS category <sup>#</sup>	Period	Peak inflow (m <sup>3</sup> s <sup>-1</sup> )
1	SEPAT	5	2007/08/16~08/19	1844.40
2	KROSA	4	2007/10/04~10/07	5300.39
3	KALMAEGI	2	2008/07/16~07/18	203.13
4	SINLAKU	4	2008/09/11~09/16	3351.24
5	MORAKOT	1	2009/08/05~08/10	1837.54
6	WIPHA	4	2007/09/17~09/19	2788.15
7	FUNG-WONG	2	2008/07/26~07/29	2039.78
8	JANGMI	5	2008/09/26~09/29	3291.99

<sup>#</sup> Hurricanes are separated into five categories based on wind strength. The scale is roughly logarithmic: 1) Very dangerous winds will cause some damage; 2) Extremely dangerous winds will cause extensive damage; 3) Devastating damage will occur; 4) Catastrophic damage will occur; 5) Catastrophic damage will occur.

Table 2 Summary statistics for reservoir inflow (m<sup>3</sup> s<sup>-1</sup>) and gauged rainfall (mm hr<sup>-1</sup>) datasets

	Mean	St.dev	Max	Min
<b>Inflow</b>	1108.90	1030.90	5300.40	10.84

Rain Gauge	Mean	St.dev	Max	Min
<b>G1</b>	6.4	8.3	53.0	0.0
<b>G2</b>	7.3	9.4	50.0	0.0
<b>G3</b>	7.4	9.6	56.0	0.0
<b>G4</b>	8.7	10.5	56.0	0.0
<b>G5</b>	7.5	8.9	52.5	0.0
<b>G6</b>	7.1	7.8	44.0	0.0
<b>G7</b>	7.8	10.0	55.0	0.0
<b>G8</b>	7.3	8.8	49.5	0.0
<b>G9</b>	7.3	8.1	62.0	0.0
<b>G10</b>	9.1	10.1	56.0	0.0
<b>G11</b>	7.6	9.3	54.0	0.0
<b>G12</b>	9.2	9.8	54.0	0.0

Table 3 Modelling configurations

Model	Inflow Output	Inflow Inputs		Rain Gauge Inputs		Radar Inputs	
		$Q_{t+1} \dots Q_{t+5}$	$Q_t$	$Q_t - Q_{t-1}$	$G_1, G_2 \dots G_{12}$	Lags (Hours)	(Sub)Catchment Units
