Abstract

Background

Supporting recovery is the aim of national mental health policy in many countries, including England. There is a need for standardised measures of recovery, to assess policy implementation and inform clinical practice. Only one measure of recovery has been developed in England: the Questionnaire about the Process of Recovery (QPR) which measures recovery from the perspective of adult mental health service users with a psychosis diagnosis.

Aims

To independently evaluate the psychometric properties of the 15-item and 22-item versions of QPR.

Method

Two samples were used: Dataset 1 (n=88) involved assessment of QPR at baseline, two weeks and three months. Dataset 2 (n=399; ISRCTN02507940) involved assessment of QPR at baseline and one year.

Results

For the 15-item version, internal consistency was 0.89, convergent validity was 0.73, test-retest reliability was 0.74 and sensitivity to change was 0.40. Confirmatory factor analysis showed the 15-item version offered a good fit. For the 22 item version comprising two sub-scales, the Interpersonal sub-scale was found to under-perform and the Intrapersonal sub-scale overlaps substantially with the 15 item version.

Conclusions

Both the 15-item and the Intrapersonal sub-scale of the 22-item versions of the QPR demonstrated satisfactory psychometric properties. The 15-item version is slightly more robust and also less burdensome, so it can be recommended for use in research and clinical practice.

Declaration of interest

None.

Introduction

Personal recovery has been defined as '*a deeply personal, unique process of changing one's attitudes, values, feelings, goals, skills, and/or roles. It is a way of living a satisfying, hopeful, and contributing life even with limitations caused by illness*' (1) .

Supporting personal recovery has become a mental health policy goal in many countries (2). Research in recent years has helped to further define recovery (3) and propose a conceptual framework of recovery oriented practice (4). Measures are required to evaluate and assess how staff and services can support recovery, from the viewpoint of people who use these services. Outcome measures have been developed to assess personal recovery (5, 6). Only one measure of recovery has been developed in England – the Questionnaire about the Process of Recovery (QPR) (7). Initial psychometric evaluation of the QPR by its developers showed good internal consistency, construct validity and test-retest reliability. An exploratory factor analysis identified two factors which were labelled 'intrapersonal' and 'interpersonal'. A subsequent re-evaluation of the QPR, conducted by its developers, found similar results and a 15-item one factor solution (8). The current study was undertaken to investigate whether these findings could be replicated in a different sample, and which of the original 22 item version or the 15 item version can be recommended. The aims were to independently evaluate the internal consistency, convergent validity, two-week test-retest reliability, three-month and 12-month sensitivity to change of both the 22 item and 15 item versions of the QPR, and to explore the factor structure of both versions.

Methods

Design

Data from two studies were used. Dataset 1 came from a psychometric evaluation study in South London, with data collected between March 2011 and May 2012. Dataset 2 is pooled baseline and one-year follow-up data from a cluster randomised controlled trial of a pro-recovery intervention(9) (ISRCTN02507940), with data from each team (cluster) collected between April 2011 and December 2013. Ethical approval was obtained for both studies.

Participants

Participants were recruited from adult community mental health teams. Inclusion criteria were (a) aged between 18-65, (b) well enough to participate and able to complete measures in the view of staff, (c) able to give informed consent, and (d) were

able to speak and understand English well enough to complete the measures. Additional inclusion criteria for dataset 1 was any mental disorder and for dataset 2 was a diagnosis of psychosis.

Procedures

Participants were recruited via their care co-ordinator from community adult mental health teams in South London (Dataset 1 and 2) and Gloucestershire (Dataset 2). All participants received payment of £10 for each round of data collection.

Dataset 1 comprised a convenience sample with care co-ordinators identifying people on their caseload who matched the inclusion criteria and who would be willing to participate. Willing participants were then contacted by a researcher who explained the study and answered any questions, before taking informed consent. Participants completed measures with a researcher at three time points: baseline, two weeks and three months. At baseline, participants completed a battery of measures including the QPR (22-item version), WEMWBS and RAS. Two weeks later, they completed the QPR. Three months after baseline they completed the QPR and WEMWBS. If participants did not complete the measures at the two week point, they were still invited to complete the measures at the three month point.

For Dataset 2, the caseload for each team was randomly ordered. Researchers then contacted the care co-ordinator of each randomised person in sequence until the required 15 participants per team were recruited. The recruitment procedure was as per Dataset 1. Participants completed an extensive assessment battery including the QPR (22-item version) and WEMWBS at baseline. One year later participants completed the same assessment battery including the QPR and WEMWBS.

Measures

The original Questionnaire about the Process of Recovery (QPR) is a 22-item, service user-rated measure of personal recovery developed in the UK (7). The measure was developed from a qualitative study led by service user-researchers. Each item is scored using a 5-point Likert scale ranging from 0 (disagree strongly) to 4 (agree strongly). The initial version comprised two sub-scales: QPR Intrapersonal (17 items) (range 0-68) and QPR Interpersonal (5 items) (range 0-20), with higher scores

indicating increased recovery in both subscales. Adequate internal consistency (Intrapersonal $\alpha = 0.94$, Interpersonal $\alpha = 0.77$), construct validity, and test-retest reliability (Intrapersonal $r = 0.87$, Interpersonal $r = 0.76$) were shown. A subsequent evaluation by the developers of the psychometric properties using a new dataset found a 15-item (range 0-60) one factor solution called QPR Total, which demonstrated adequate internal consistency ($\alpha = 0.93$) and test-retest reliability using Pearson's correlation ($r = 0.70$) (8). In this study both datasets were collected using the 22-item QPR, with the 15-item QPR Total score being extrapolated. In this analysis we refer to the two sub-scales of the 22 item QPR as QPR Intrapersonal and QPR Interpersonal, and the 15-item QPR as QPR Total.

The Recovery Assessment Scale (RAS) is a 41-item service user-rated measure assessing five domains of recovery: personal confidence and hope, willingness to ask for help, goal and success orientation, reliance on others and no domination by symptoms (10). Each item is scored on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree) with the total score ranging from 41 (low recovery) to 205. Good internal consistency of $\alpha = 0.93$ and test-retest reliability using Pearson's correlation of $r = 0.88$ have been demonstrated (10).

The Warwick-Edinburgh Wellbeing Scale (WEMWBS) is a 14-item self-report measure assessing well-being (11). Respondents rate their experience regarding each statement over the last two weeks. Each item is scored using a 5-point Likert scale ranging from 1 (None of the time) to 5 (All of the time) with the total score ranging from 14 (low well-being) to 70. In the initial validation study, good content validity, internal consistency of $\alpha = 0.89$, and test-retest reliability using intra-class correlation coefficients of $r = 0.83$ were demonstrated (11). The measure has also been validated with adolescent and minority ethnic groups (12).

Analysis

Using Dataset 1, convergent validity was assessed using Pearson's correlation between RAS and QPR Intrapersonal, QPR Interpersonal and QPR Total at baseline. Test-retest reliability was assessed by exploring agreement at the individual level using two-way random effects intraclass correlations between QPR Intrapersonal, QPR Interpersonal and QPR Total at baseline and two weeks. Sensitivity to change was

assessed using the correlation between QPR Intrapersonal, QPR Interpersonal and QPR Total and WEMWBS change scores from baseline to 3-month follow-up.

Using Dataset 2, internal consistency was assessed using Cronbach's alpha. Sensitivity to change was assessed using the association between QPR Intrapersonal, QPR Interpersonal and QPR Total and WEMWBS change scores between baseline and 12-month follow-up. This was achieved by regressing each QPR scale change score onto the WEMWBS while accounting for clustering at the team level by using the 'xtmixed' command with maximum likelihood estimation in Stata 11. Site and study arm were entered as covariates in the model in order to reflect the study design. Prior to conducting the regression analysis, change scores were standardised (mean=0, SD=1) to obtain a standardised regression coefficient which is equivalent to a regression coefficient. All analyses were conducted on complete cases using Stata Version 11.

Two separate confirmatory factor analyses were conducted to assess the fit of baseline data (a) to QPR Total (using the one-factor solution previously identified (8), and (b) to QPR Interpersonal and QPR Intrapersonal (using the 2-factor solution previously identified (7)). The CFA analyses were conducted in Mplus 7.2 using the weighted least squares mean variance (WLSMV) estimator (13), taking into account clustering at the team level and adjusting the model for NHS Trust as this captures the study design. Goodness of fit was assessed using several fit indices: χ^2 ($p > .05$), Root Mean Square Error of Approximation (RMSEA $< .06$), Tucker-Lewis Index (TLI $> .95$) and Comparative Fit Index (CFI $> .95$).

Results

Participants

Demographics and QPR scores for both samples are shown in Table 1.

Insert Table 1 here

The two samples did not differ in sociodemographic characteristics, other than Dataset 1 had a higher number of participants from Black ethnic background ($\chi^2_{(2)}= 10.7$, $p=.005$).

Convergent validity

In Dataset 1 ($n=76$), the baseline RAS score was positively correlated with baseline QPR Interpersonal ($r=0.46$, 95% CI: 0.26 to 0.67, $p<0.001$), QPR Intrapersonal ($r=0.75$, 95% CI 0.63 to 0.83, $p<0.001$) and QPR Total ($r=0.73$, 95% CI 0.61 to 0.82, $p<0.001$), indicating adequate convergent validity for each scale.

Test-retest reliability

Intraclass-correlations in Dataset 1 ($n=91$) between baseline and two weeks was 'good' for QPR Interpersonal (ICC=0.66, 95%CI: 0.53 to 0.77) and QPR Intrapersonal (ICC=0.75, 95%CI: 0.64 to 0.83), and 'fair to good' for QPR Total (ICC=0.74, 95%CI: 0.63 to 0.82).

Sensitivity to change

The sensitivity to change of QPR was tested using WEMWBS as a comparator, as shown in Table 2.

Insert Table 2 here

Sensitivity to change in both datasets was moderate for QPR Intrapersonal and QPR Total, and low for QPR Interpersonal.

Internal consistency

Cronbach's alpha coefficients for baseline scores in Dataset 2 ($n=399$) indicated excellent internal consistency for QPR Total ($\alpha=0.89$) and the QPR Intrapersonal sub-scale ($\alpha=0.90$). However, internal consistency for QPR Interpersonal was poor ($\alpha=0.49$).

Factor structure

As a first step, we fitted a 1-factor model in dataset 2 ($n=399$) for QPR total, finding an adequate fit ($\chi^2_{(90)}=233.2$, $p<0.001$; RMSEA=0.063, 90%CI: .05 to .07; CFI=.97;

TLI=.97). Table 3 shows the standardised loadings for all 15 items showing that all items load onto the factor.

Insert Table 3 here

We then fitted a 2-factor model for the two QPR subscales (Intrapersonal and Interpersonal), also shown in Table 2. This model also offered a good fit ($\chi^2_{(208)}=407.5$, $p<.001$; RMSEA=.049, 90%CI: .04 to .06; CFI=.96; TLI=.96), although items 20 and 22 had low factor loadings, indicating they are weakly associated with the latent construct.

Discussion

The study used two samples to evaluate the psychometric properties of the two subscales of the 22 item version (QPR Intrapersonal and QPR Interpersonal) and the 15 item version (QPR Total). Both QPR Intrapersonal and QPR Total demonstrated adequate psychometric properties, whereas QPR Interpersonal did not demonstrate psychometric adequacy.

QPR Intrapersonal demonstrated excellent psychometric properties in all areas tested, apart from moderate sensitivity to change. All items had a loading above 0.5 in the confirmatory factor analysis, indicating they capture the intrapersonal scale. By contrast, the QPR Interpersonal sub-scale had poor internal consistency and sensitivity to change and the factor analysis found that two of the five items – item 16 ‘Meeting people who have had similar experiences makes me feel better’ and item 20 ‘I realise that the views of some mental health professionals is not the only way of looking at things’ – had a factor loading below 0.5. This indicates that they are weakly associated with the latent construct and, therefore, do not describe it very well. Anecdotally, we found that Item 20 was more difficult for participants to answer, due to asking about the view of ‘some’ professionals which participants found confusing. Overall, these results indicate that QPR Interpersonal is not well defined, and constructs with five or more items are generally recommended to define a robust construct (14).

The 15-item QPR Total demonstrated excellent internal consistency and test-retest reliability, adequate convergent validity, and moderate sensitivity to change. These findings reflect those of Law and colleagues in their paper which recommended the 15

item version of QPR (8). In this paper the 15 item version had a Cronbach's alpha of 0.93 and good test-retest reliability ($r=0.70$). In our paper the CFA found that all items loaded above 0.5. As all of the 15 items are in the QPR Intrapersonal sub-scale, there is a great deal of overlap between QPR Total and QPR Intrapersonal.

Strengths and limitations

The study provides a comprehensive and independent psychometric evaluation of the QPR, including being the first study to evaluate sensitivity to change. It is also the first study to compare the two versions of QPR. The limitation of this study is that one of our samples was relatively small. The use of two datasets (although similar in demographic characteristics) can also be seen as a limitation, as can the non-collection of important clinical descriptive data such as illness severity and duration. However, each dataset had advantages, with Dataset 1 allowing evaluation of test-retest reliability at two weeks, and the sample in Dataset 2 sufficiently large to allow CFA.

QPR in clinical practice

We identify three clinical implications. First, the QPR can be used to measure the effectiveness of services in supporting recovery. Evidence on how best to support recovery is still developing (4) (9), and there is as yet little evidence on the impact of recovery support on recovery outcomes. Having a robust tool to measure recovery will contribute to this goal.

Secondly, the results suggest that the QPR may have a role in benchmarking services and comparing the effectiveness of interventions. Sensitivity to change for QPR Total was moderate. Although this provides stronger evidence than for other recovery measures (5), a robust understanding of processes impacting on sensitivity to change is needed. The absence of longitudinal studies of personal recovery mean that the level of likely change in recovery is unknown. At one extreme, recovery may be a highly stable construct, consistent with set point theory which finds that subjective ratings of well-being quickly return to baseline levels, even after life events cause a temporary change (15) . At the other extreme, recovery may be highly unstable and influenced by a range of intrapersonal, interpersonal and social determinants. Given the measurement challenges inherent to subjective rating scales, the minimally important difference estimate of responsiveness should be established before QPR is

used for service evaluation. The QPR has been recommended by the Implementing Recovery through Organisational Change (ImROC) initiative as part of a suite of measures to assess recovery support (16). Robust measures of recovery support such as INSPIRE (17) can be used in conjunction with the QPR to assess the relationship between recovery support and the experience of recovery.

Third, Government policy in England has become more outcome-focused (2) and the introduction of the Payment by Results funding system in mental health services may lead to outcome measurement being more widely introduced. As recovery is a policy aim, services may need to routinely measure recovery. Furthermore, there is a growing interest in the use of Patient Reported Outcome Measures (PROMs) such as the QPR in mental health services (18).

QPR in research

The relationship between recovery and other outcomes in mental health is still being explored (19), and standardised measures of recovery are needed. One issue for the measurement of recovery is ensuring that recovery measures have a robust conceptual underpinning (20). An empirical understanding of key recovery processes is emerging, such as the CHIME framework which identifies recovery processes of Connectedness, Hope, Identity, Meaning and Purpose, and Empowerment (3). A systematic review of recovery measures which used the CHIME Framework to identify the breadth of coverage of recovery measures, indicated that the QPR had the best spread of items covering the five processes, suggesting that the QPR is measuring these aspects of recovery (5).

We identify two key knowledge outcomes from this study. Firstly, the 15-item QPR Total scale can be recommended for use in research and clinical practice. Our recommendation reflects its adequate psychometrics, lower burden compared with the 22-item version, and easier interpretation (as a total score, rather than two sub-scales). A shorter version reduces the burden on respondents which is an advantage (21) as people who use services do not like having to complete long outcome measures (22). Specifically, a shorter measure makes it more feasible for use, thus increasing the likelihood of completion (23). Future work could evaluate the implications of measuring recovery as a unidimensional construct, using analytic methods such as Item Response Theory or Rasch Measurement Theory.

Secondly, we found preliminary evidence of sensitivity to change. This is a key psychometric property currently under-researched in measures of recovery change (5). Our results provide some evidence of the ability of the QPR to measure change, suggesting that QPR can be used in longitudinal research and to assess change in a clinical setting. Future research will need to identify a gold standard for evaluating this property, but it is encouraging that there was a correlation with change in two measures assessed at two different time points.

Measuring the recovery of people using mental health services using standardised measures is one method that can be used to assess the effectiveness of services in supporting recovery. Robust measures of recovery are needed to do this. Overall, the 15-item QPR version is a valuable contribution to the measurement of recovery.
