Uncertain data streams have been widely generated in many Web applications. The uncertainty in data streams makes anomaly detection from sensor data streams far more challenging. In this paper, we present a novel framework that supports anomaly detection in uncertain data streams. The proposed framework adopts an efficient uncertainty pre-processing procedure to identify and eliminate uncertainties in data streams. Based on the corrected data streams, we develop effective period pattern recognition and feature extraction techniques to improve the computational efficiency. We use classification methods for anomaly detection in the corrected data stream. We also empirically show that the proposed approach shows a high accuracy of anomaly detection on a number of real datasets.

Categories and Subject Descriptors: I.5.4 [**Pattern recognition**]: Applications

General Terms: Design, Algorithms, Performance

Additional Key Words and Phrases: anomaly detection, uncertain data stream, segmentation, classification

1. INTRODUCTION

Data streams have been widely generated in many Web applications such as monitoring click streams [Gündüz and Özsu 2003], stock tickers [Chen et al. 2000; Zhu and Shasha 2002], sensor data streams and auction bidding patterns [Arasu et al. 2003]. For example, in the applications of Web tracking and personalization, Web log entries or click-streams are typical data streams. Other traditional and emerging applications include wireless sensor networks (WSN) in which data streams collected from sensor networks are being posted directly to the Web. Typical applications comprise environment monitoring (with static sensor nodes) [Akyildiz et al. 2005] and animal and object behaviour monitoring (with mobile sensor nodes), such as water pollution detection [He et al. 2012] based on water sensor data, agricultural management and cattle moving habits [CSIRO 2011], and analysis of trajectories of animals [Gudmundsson et al. 2007], vehicles [Zheng et al. 2010] and fleets [Lee et al. 2007].

Anomaly detection is a typical example of a data streams application. Here, anomalies or outliers or exceptions often refer to the patterns in data streams that deviate expected normal behaviours. Thus, anomaly detection is a dynamic process of finding abnormal behaviours from given data streams. For example, in medical monitoring applications, a human electrocardiogram (ECG) (vital signs) and other treatments and

DOI:http://dx.doi.org/10.1145/0000000.0000000

measurements are typical data streams that appear in a form of periodic patterns. That is, the data present a repetitive pattern within a certain time interval. Such data streams are called pseudo periodic time series. In such applications, data arrives continuously and anomaly detection must detect suspicious behaviours from the streams such as abnormal ECG values, abnormal shapes or exceptional period changes.

Uncertainty in data streams makes the anomaly detection far more challenging than detecting anomalies from deterministic data. For example, uncertainties may result from missing points from a data stream, missing stream pieces, or measurement errors due to different reasons such as sensor failures and measurement errors from different types of sensor devices. This uncertainty may cause serious problems in data stream mining. For example, in an ECG data stream, if a sensor error is classified as abnormal heart beat signals, it may cause a serious misdiagnosis. Therefore, it is necessary to develop effective methods to distinguish uncertainties and anomalies, remove uncertainties, and finally find accurate anomalies.

There are a number of related research areas to sensor data stream mining, such as data streams compression, similarity measurement, indexing and querying mechanisms [Esling and Agon 2012]. For example, to clean and remove uncertainty from data, a method for compressing data streams was presented in [Douglas and Peucker 1973]. This method uses some critical points in a data stream to represent the original stream. However, this method cannot compress uncertain data streams efficiently because such compression may result in an incorrect data stream approximation and it may remove useful information that can correct the error data.

This paper focuses on anomaly detection in uncertain pseudo periodic time series. A pseudo periodic time series refers to a time-indexed data stream in which the data present a repetitive pattern within a certain time interval. However, the data may in fact show small changes between different time intervals. Although much work has been devoted to the analysis of pseudo periodic time series [Keogh et al. 2005; Huang et al. 2014], few of them focus on the identification and correction of uncertainties in this kind of data stream.

In order to deal with the issue of anomaly detection in uncertain data streams, we propose a supervised classification framework for detecting anomalies in uncertain pseudo periodic time series, which comprises four components: a uncertainty identification and correction component (UICC), a time series compression component (TSCC), a period segmentation and summarization component (PSSC), and a classification and anomaly detection component (CADC). First, UICC processes a time series to remove uncertainties from the time series. Then TSCC compresses the processed raw time series to an approximate time series. Afterwards the PSSC identifies the periodic patterns of the time series and extracts the most important features of each period, and finally the CADC detects anomalies based on the selected features. Our work has made the following distinctive contributions:

— We present a classification-based framework for anomaly detection in uncertain pseudo periodic time series, together with a novel set of techniques for segmenting and extracting the main features of a time series. The procedure of pre-processing uncertainties can reduce the noise of anomalies and improve the accuracy of anomaly detection. The time series segmentation and feature extraction techniques can improve the performance and time efficiency of classification.
— We propose the novel concept of a feature vector to capture the features of the turning points in a time series, and introduce a silhouette value based approach to identify the periodic points that can effectively segment the time series into a set of consecutive periods with similar patterns.

— We conduct an extensive experimental evaluation over a set of real time series data sets. Our experimental results show that the techniques we have developed outperform previous approaches in terms of accuracy of anomaly detection. In the experiment part of this paper, we evaluate the proposed anomaly detection framework on ECG time series. However, due to the generic nature of features of pseudo periodic time series (e.g. similar shapes and intervals occur in a periodic manner), we believe that the proposed method can be widely applied to periodic time series mining in different areas.

The structure of this paper is as follows: Section 2 introduces the related research work. Section 3 presents the problem definition and generally describes the proposed anomaly detection framework. Section 4 describes the anomaly detection framework in detail. Section 5 presents the experimental design and discusses the results. Finally, Section 6 concludes this paper.

2. RELATED WORK

We analyse the related research work from two dimensions: anomaly detection and uncertainty processing.

Anomaly detection in data streams: Anomaly detection in time series has various applications in wide area, such as intrusion detection [Tavallaee et al. 2010], disease detection in medical sensor streams [Manning and Hudgins 2010], and biosurveillance [Shmueli and Burkom 2010]. Zhang et al.[ling Zhang et al. 2009] designed a Bayesian classifier model for identification of cerebral palsy by mining gait sensor data (stride length and cadence). In stock price time series, anomalies exist in a form of change points that reflect the abnormal behaviors in the stock market and often repeating motifs are of interest [Wilson et al. 2008]. Detecting change points has significant implications for conducting intelligent trading [Jiang et al. 2011]. Liu et al. [Liu et al. 2010] proposed an incremental algorithm that detects changes in streams of stock order numbers, in which a Poisson distribution is adopted to model the stock orders, and a maximum likelihood (ML) method is used to detect the distribution changes.

The segmentation of a time series refers to the approximation of the time series, which aims to reduce the time series dimensions while keeping its representative features [Esling and Agon 2012]. One of the most popular segmentation techniques is the Piecewise Linear Approximation (PLA) based approach [Keogh et al. 2004; Qi et al. 2015], which splits a time series into segments and uses polynomial models to represent the segments. Xu et al. [Xu et al. 2012] improved the traditional PLA based techniques by guaranteeing an error bound on each data point to maximally compact time series. Daniel [Lemire 2007] introduced an adaptive time series summarization method that models each segment with various polynomial degrees. To emphasize the significance of the newer information in a time series, Palpanas et al. [Palpanas et al. 2008] defined user-oriented amnesic functions for decreasing the confidence of older information continuously.

However, the approaches mentioned above are not designed to process and adapt to the area of pseudo periodic data streams. Detecting anomalies from periodic data streams has received considerable attention and several techniques have been proposed recently [Folarin et al. 2001; Grinsted et al. 2004; Levy and Pappano 2007]. The existing techniques for anomaly detection adopt sliding windows [Keogh et al. 2005; Gu et al. 2005] to divide a time series into a set of equal-sized sub-sequences. However, this type of method may be vulnerable to tiny difference in time series because it cannot well distinguish the abnormal period and a normal period having small noisy data. In addition, as the length of periods is varying, it is difficult to capture the periodicity by using a fixed-size window [an Tang et al. 2007]. Other examples of

Table I. Frequently Used Symbols

Symbols	Meaning
TS	A time series
p_i	The ith point in a TS
SS	A subsequence
PTS	A pseudo periodic time series
Q	A set of period points in a PTS
pd	A period in a PTS
CTS	A compressed PTS
$diff_i$	$diff_{1i} = t_i - t_{i-1}$, $diff_{2i} = t_{i+1} - t_i$
vec_i	A feature vector of point p_i
$sil(p_i)$	Silhouette value of point p_i
$sim(p_i, p_j)$	Euclidean distance based similarity between points p_i and p_j
C	A set of clusters
$msil(C)$	Mean silhouette value of a cluster C
seg_i	A summary of a period
STS	A segmented CTS
A_{STS}	A set of annotations
Lbs	A set of labels indicating the states
$lb_{(i)}$	The ith label in Lbs_{PTS}

segmenting pseudo periods include an peak-point-based clustering method and valley-point-based method [Huang et al. 2014; an Tang et al. 2007]. These two methods may have very low accuracy when the processed time series have noisy peak points or have irregularly changed sub-sequences. Our proposed approach falls into the category of classification-based anomaly detection, which is proposed to overcome the challenge of anomaly detection in periodic data streams. In addition, our method is able to identify qualified segmentation and assign annotation to each segment to effectively support the anomaly detection in a pseudo periodic data streams.

Uncertainty processing in data streams: Most data streams coming from real-world sensor monitoring are inherently noisy and uncertainties. A lot of work has concentrated on the modelling of uncertain data streams [Aggarwal and Yu 2008; Aggarwal 2009; Leung and Hao 2009]. Dallachiesa et al.[Dallachiesa et al. 2012] surveyed recent similarity measurement techniques of uncertain time series, and categorized these techniques into two groups: probability density function based methods [Sarangi and Murthy 2010] and repeated measurement methods [Aßfalg et al. 2009]. Tran et al.[Tran et al. 2012] focused on the problem of relational query processing on uncertain data streams. However, previous work rarely focused on the detection and correction of the missing critical points for a discrete time series. In this work, we model a continuous time series as a discrete time series by identifying the critical points in a time series, and introduce a novel method of detecting and correcting the missing inflexions based on the angles between points.

3. PROBLEM SPECIFICATION AND FRAMEWORK DESCRIPTION

In this section, we first give a formal definition of the problems and then describe the proposed framework of detecting abnormal signals in uncertain time series with pseudo periodic patterns. The symbols frequently used in this paper are summarized in Table I.

3.1. Problem definition

Definition 3.1. A **time-series** TS is an ordered real sequence: $TS = (v_1, \cdots, v_n)$, where v_i, $i \in [1, n]$, is a point value on the time series at time t_i.

We use the form $|TS|$ to represent the number of points in time series TS (i.e., $|TS| = n$). Based on the above definition, we define subsequence of a TS as below.

Definition 3.2. For time series TS, if $SS(\subset TS)$ comprises m consecutive points: $SS = (v_{s_1}, \cdots, v_{s_m})$, we say that SS is a **subsequence** of TS with length m, represented as $SS \sqsubseteq TS$.

Definition 3.3. A **pseudo periodic time series** PTS is a time series $PTS = (v_1, v_2, \cdots, v_n)$, $\exists Q = \{v_{p_1}, \cdots, v_{p_k} | v_{p_i} \in PTS, i \in [1,k]\}$, that regularly separates PTS on the condition that

(1) $\forall i \in [1, k-2]$, if $\triangle_1 = |p_{i+1} - p_i|, \triangle_2 = |p_{i+2} - p_{i+1}|$, then $| \triangle_2 - \triangle_1 | \leq \xi_1$; where ξ_1 is a small value.
(2) let $s_1 = (v_{p_i}, v_{(p_i)+1}, \cdots, v_{p_{i+1}}) \sqsubseteq PTS$, and $s_2 = (v_{p_{i+1}}, v_{(p_{i+1})+1}, \cdots, v_{p_{i+2}}) \sqsubseteq PTS$, then $dsim(s1, s2) \leq \xi_2$, where $dsim()$ calculates the dis-similarity between $s1$ and $s2$, and ξ_2 is a small value. $dsim()$ can be any dis-similarity measuring function between time series, e.g., Euclidean distance.

In particular, $v_{p_{i+1}} \in Q$ is called a period point.

An uncertain PTS is a PTS having error detected data or missing points.

Definition 3.4. If $pd \sqsubseteq PTS$, and $pd = (v_{p_i}, v_{(p_i)+1}, \cdots, v_{p_{i+1}}), \forall v_{p_i} \in Q$, then pd is called a **period** of the PTS.

Definition 3.5. A **normal pattern** M of a PTS is a model that uses a set of rules to describe a behaviour of a subsequence SS, where $m = |SS|$ and $m \in [1, |PTS|/2]$. This behaviour indicates the normal situation of an event.

Based on the above definitions, we describe types of anomalies that may occur in a PTS. There are two possible types of anomalies in a PTS: local anomalies and global anomalies Given the PTS in Definition 3.3, and a normal pattern $N = (v_1, \cdots, v_m) \sqsubseteq PTS$, a local anomaly (L) is defined as:

Definition 3.6. Assume $L = (v_{l_1}, \cdots, v_{l_n}) \sqsubseteq PTS$, L is a local anomaly if either of the two conditions in Definition 3.3 is broken (shown as below (1)), and at the same time satisfies the following two conditions (below (3)):

(1) $\triangle_N - \triangle_L > \xi_1$ or $dsim(N, L) > \xi_2$;
(2) frequency of L: $freq(L) \ll freq(N)$ and L does not happen in a regular sampling frequency.
(3) $|L| \ll |PTS|$.

Example 3.7. Fig.1 shows two examples of pseudo periodic time series and their local anomalies. Fig.1(a) shows a premature ventricular contraction signal in an ECG stream. A premature ventricular contraction (PVC) [Levy and Pappano 2007] is perceived as a "skipped beat". It can be easily distinguished from a normal heart beat when detected by the electrocardiogram. From Fig.1(a), the QRS and T waves of a PVC (indicated by V) are very different from the normal QRS and T (indicated by N). Fig.1(b) presents an example of premature atrial contractions (PACs)[Folarin et al. 2001]. A PAC is a premature heart beat that occurs earlier than the regular beat. If we use the highest peak points as the period points, then a segment between two peak points is a period. From Fig.1, the second period (a PAC) is clearly shorter than the other periods.

3.2. Overview of the Anomaly Detection Framework for Uncertain Time Series Data

As mentioned previously, the proposed framework comprises four main components: an uncertainty identification and correction component (UICC), a time series compression component (TSCC), a period segmentation and summarization component (PSSC),

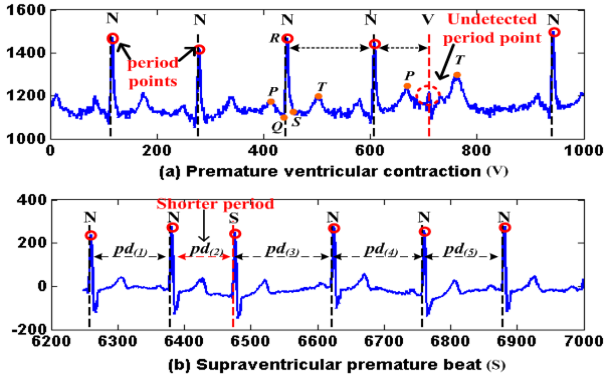

Fig. 1. Two examples of local anomaly in ECG time series

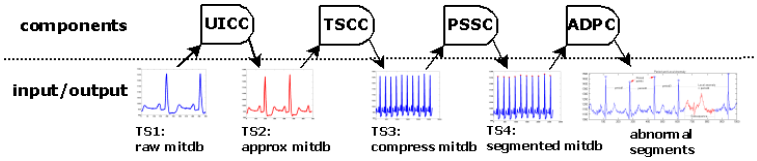

Fig. 2. Workflow of the $mitdb$ processing based on the proposed framework

and an anomaly detection and prediction component (ADPC). We explain the process of anomaly detection of the proposed framework using an example of the dataset $mitdb$. Fig.2 shows the processing progress of $mitdb$. First, the raw $mitdb$ time series is an input to the UICC component. The TS1 in Fig.2 shows a subsequence of the raw $mitdb$. The UICC identifies the inflexions (including missing inflexions) of $mitdb$, and the raw $mitdb$ is transformed into an approximated time series that only consists of the identified inflexions (TS2 in Fig.2). The TSCC component then further compresses the approximated $mitdb$. The TS3 in Fig.2 shows the compressed time series (CTS) that is a compression of the subsequence in TS2. The PSSC component segments the time series and assigns annotations to each segment. TS4 in Fig.2 shows the segmented and annotated CTS corresponding to the CTS in TS3. Finally, the ADPC component learns a classification model based on the segmented CTS to detect abnormal subsequences in similar time series.

In the next section, we introduce the framework and its four components in detail.

4. ANOMALY DETECTION IN UNCERTAIN PERIODIC TIME SERIES

4.1. Uncertainty Identification and Correction: UICC

In this section, we introduce the procedure of eliminating uncertainties of a PTS caused by non-captured key-points of a PTS, based on our previous work [He et al. 2013]. We first introduce the definition of key-points of a time series.

Definition 4.1. Given a $PTS = (v_1, \cdots, v_n)$, if a point, $p_i = v_1$ or v_n, is a turning point, then p_i is a key-point; or else, if $\angle p_i = \pi - \angle p_j p_i p_k$ and $\angle p_i > \epsilon$, where $\angle p_i$ is the angle between vectors $\overrightarrow{p_j p_i}$ and $\overrightarrow{p_i p_k}$, $2 \leq j < i < k \leq n$, ϵ is a threshold, p_j and p_k are key-points, and for any point $p_r, j < r < k$, $\angle p_r \leq \epsilon$, then p_i is a key-point.

From the above definition, the core procedure to determine a point p_k as a key-point is based on the angles between $\overrightarrow{p_{k-1} p_k}$ and $\overrightarrow{p_k p_{k+1}}$($i.e.$, $\angle p_k = \pi - \angle p_{k-1} p_k p_{k+1}$), given that p_{k-1} and p_{k+1} are both key-points. If $\angle p_k$ is larger than a threshold value, and

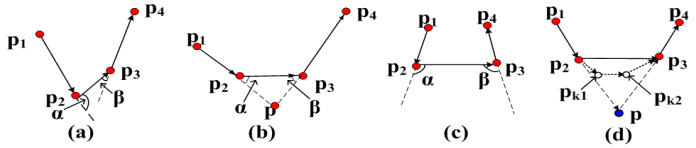

Fig. 3. (a) p_2 is a key-point. (b) p is a missing key-point. (c) p_2 and p_3 are two key-points. (d) p_{k1} and p_{k2} are two missing key-points, while p is one deduced key-point.

the angles of all the other points between $k-1$ and $k+1$ are not larger than the threshold, then p_k is a key-point. However, if p_k is missing, we need to check at least four points: two key-points before and two key-points after p_k respectively. Therefore, we generally check four consecutive points at the same time. Combined with Fig.3, the detailed process is described below:

Given four consecutive points $p_1 = v_1$, $p_2 = v_2$, $p_3 = v_3$, and $p_4 = v_4$, where p_1 and p_4 are key-points, and a small value $\epsilon \to 0$, let $\angle p_2 = \pi - \angle p_1p_2p_3$ and $\angle p_3 = \pi - \angle p_2p_3p_4$,

— If $\angle p_2 > \epsilon$, $\angle p_3 < \epsilon$, and there is no other point between p_1 and p_4, then p_2 is a key-point (see Fig.3(a));
— If $\angle p_2 < \epsilon$, and $\angle p_3 > \epsilon$, then p_3 is a key-point;
— If $\angle p_2 > \epsilon$, $\angle p_3 > \epsilon$, and $\angle p_2 + \angle p_3 < \pi$, then there may be a missing key-point. In this case, it is also possible that both of p_2 and p_3 are key-points. If we can find a missing point $p = v$ at time t, that $\angle p = \angle p_2 + \angle p_3 \geq 2 * \epsilon$, then the point p is more likely to be a key-point between p_2 and p_3, as the larger $\angle p$ indicates the larger turning degree of the time series at point p. We deduce missing key-points by solving the equation $Q = \frac{|p_2p|}{sin(\angle p_3)} = \frac{|p_3p|}{sin(\angle p_2)}$, where $Q = \frac{|p_2p_3|}{sin(\pi - \angle p_2 - \angle p_3)}$, which can be written as:

$$\begin{cases} Q^2 sin^2 \angle p_3 = (v - v_2)^2 + (t - t_2)^2 \\ Q^2 sin^2 \angle p_2 = (v - v_3)^2 + (t - t_3)^2 \end{cases} \quad (1)$$

If Equation (1) only has one solution, this solution is a key-point; if it has two solutions, we adopt the one on the line of $\overline{p_1p_2}$, i.e., p in Fig.3(b) as a key-point; if it does not have solution, point p_2 and p_3 are key-points.
— If $\angle p_2 > \epsilon$, $\angle p_3 > \epsilon$, and $\angle p_2 + \angle p_3 > \pi$, then p_2 and p_3 are both key-points (Fig.3(c)). In addition, it is impossible that there are other missing points, say p, between p_2 and p_3, that $\angle p > \epsilon$.
— If more than one consecutive key-points are missing, the above method will only detect one missing point as an representation of all the missing key-points. For example, Fig.3(c) shows p_{k12} and p_{k22} are two missing key-points, however, one virtual key-point p_2 based on the existing points p_1, p_{k11}, p_{k21}, and p_3 are deduced.

Key-points capture the critical information and fill the missing information of a PTS, hence, the detected key-points can be used to represent the raw PTS. In the sequel sections, a PTS typically refers to a series of key-points of the original PTS.

4.2. Anomaly Detection in Corrected Time Series

Anomaly detection and normal pattern identification are both processed based on the unit of $period$. The first step is to identify period points Q that separate PTS into a set of periods. We use clustering method to categorize the inflexions of a PTS into a number of clusters. Then a cluster quality validation mechanism is applied to validate the quality of each cluster. The cluster with the highest quality will be adopted as the period cluster, that is, the points in the period cluster will be the period points for

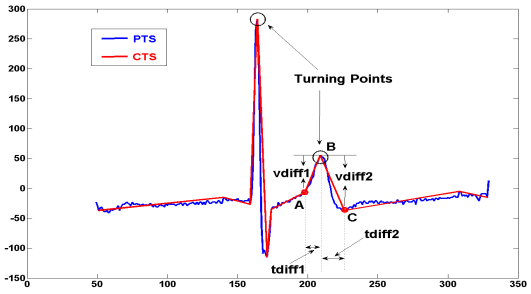

Fig. 4. A PTS and one of its $CTSs$

the time series. The period points are the points that can regularly and consistently separate the PTS better than the points in the other clusters.

The cluster quality validation mechanism is a silhouette-value based method, in which the cluster that have highest mean silhouette value will be assumed to have the best clustering pattern. To accurately conduct clustering, we introduce a feature vector for each inflexion of PTS, with the optimal intention that each point can be distinguished with others efficiently.

4.2.1. Time Series Compression: TSCC. To save the storage space and improve the calculation efficiency, the raw PTS will first be compressed. In this work, we use the Douglas–Peucker (DP) [Hershberger and Snoeyink 1994] algorithm to compress a PTS, which is defined as: (1) use line segment $\overline{p_1p_n}$ to simplify the PTS; (2) find the farthest point p_f from $\overline{p_1p_n}$; (3) if distance $d(p_f, \overline{p_1p_n}) \leq \lambda$, where λ is a small value, and $\lambda \geq 0$, then the PTS can be simplified by $\overline{p_1p_n}$, and this procedure is stopped; (4) otherwise, recursively simplify the subsequences $\{p_1, \cdots, p_f\}$ and $\{p_f, \cdots, p_n\}$ using steps $(1-3)$.

Definition 4.2. Given a $PTS = (v_1, \cdots, v_n)$, a **compressed time series** CTS of PTS is represented as $CTS = (v_{c_1}, \cdots, v_{c_n}) \subseteq PTS$, where $\forall p_{c_i} \in CTS$ is an inflexion, and $|CTS| \ll |PTS|$.

The feature vector of an inflexion is defined as:

Definition 4.3. A **feature vector** for a point $p_i \in PTS$ is a four-value vector $vec_i = (vdiff1_i, vdiff2_i, tdiff1_i, tdiff2_i)$, where $vdiff1_i = v_i - v_{i-1}$, $vdiff2_i = v_{i+1} - v_i$, $tdiff1_i = t_i - t_{i-1}$, and $tdiff2_i = t_{i+1} - t_i$.

Example 4.4. Fig.4 shows an example of a PTS and one of its compressed time series CTS. The value differences $vdiff1$ and $vdiff2$, and the time differences $wdiff1$ and $wdiff2$ are shown in Fig.4.

4.2.2. Period Segmentation and Summarization: PSSC. PSSC component identifies period points that separate the CTS into a series of periods, which is implemented by three steps: cluster points of CTS, evaluate the quality of clusters based on silhouette value, and Segment and annotate periods. Details of these steps are given below.

Step 1: Cluster Points of CTS Points are clustered into a number of clusters based on their feature vectors. In this work, we use k-means++ [Arthur and Vassilvitskii 2007] clustering method to cluster points. It has been validated that based on the proposed feature vector, the k-means++ is more accurate and less time-consumed than other clustering tools (e.g., k-means [Hartigan and Wong 1979], Gaussian mixture models [Reynolds 2009] and spectral clustering [Ng et al. 2001]). We give an brief introduction of the k-means++ in this section.

k-means++ is an improvement of k-means by first determining the initial clustering centres before conducting the k-means iteration process. k-means is a classical NP-hard clustering method. One of its drawbacks is the low clustering accuracy caused by randomly choosing the k starting points. The arbitrarily chosen initial clusters cannot guarantee a result converging to the global optimum all the time. k-means++ is proposed to solve this problem. K-mean++ chooses its first cluster center randomly, and each of the remaining ones is selected according to the probability of the point's squared distance to its closest centre point being proportional to the squared distances of the other points. The k-means++ algorithm has been proved to have a time complexity of $O(logk)$ and it is of high time efficiency by determining the initial seeding. For more details of k-means++, readers can refer to [Arthur and Vassilvitskii 2007].

Step 2: Evaluate the quality of clusters based on silhouette value. We use the mean Silhouette value[Rousseeuw 1987] of a cluster to evaluate the quality of a cluster. The silhouette value can interpret the overall efficiency of the applied clustering method and the quality of each cluster such as the tightness of a cluster and the similarity of the elements in a cluster. The silhouette value of a point belonging to a cluster is defined as:

Definition 4.5. Let points in PTS be clustered into k clusters: $C_{CTS} = \{C_1, \cdots, C_m, \cdots, C_k\}, k \leq |CTS|$. For any point $p_i = v_i \in C_m$, the silhouette value of p_i is

$$sil(p_i) = \frac{b(p_i) - a(p_i)}{max\{a(p_i), b(p_i)\}} \tag{2}$$

where $a(p_i) = \frac{1}{M-1} \sum_{p_i, p_j \in C_m, i \neq j} sim(p_i, p_j), M = |C_m|$ is the number of elements in cluster m; $b(p_i) = min(\frac{1}{M-1} \sum_{p_i \in C_m, p_j \in C_h, h \neq m} sim(p_i, p_j))$. $sim(p_i, p_j)$ represents the similarity between p_i and p_j.

In the above definition, $sim(p_i, p_j)$ can be calculated by any similarity calculation formula. In this work, we adopt the Euclidean Distance as similarity measure, i.e., $sim(p_i, p_j) = \sqrt{(v_i - v_j)^2 + (t_i - t_j)^2}$, where t_i and t_j are the time indexes of the points p_i and p_j. From the definition, $a(p_i)$ measures the dissimilarity degree between point p_i and the points in the same cluster, while $b(p_i)$ refers to the dissimilarity between p_i and the points in the other clusters. Therefore, a small $a(p_i)$ and a large $b(p_i)$ indicate a good clustering. As $-1 \leq sil(p_i) \leq 1$, a $sil(p_i) \to 1$ means that a point p_i is well clustered, while $sil(p_i) \to_+ 0$ represents the point is close to the boundary between clusters M and H, and $sil(p_i) < 0$ indicates that point p_i is close to the points in the neighbouring clusters rather than the points in cluster M.

The mean value of the silhouette values of points is used to evaluate the quality of the overall clustering result: $msil(C_{CTS}) = \frac{1}{|CTS|} \sum_{p_i \in CTS} sil(p_i)$. Similar to the silhouette value of a point, the $msil \to 1$ represents a better clustering.

After clustering, we need to choose a cluster in which the points will be used as period points for the CTS. The chosen cluster is called **period cluster**. The points in the period cluster are the most stable points that can regularly and consistently separate CTS. We use the mean silhouette value of each cluster to evaluate the efficiency of a single cluster, represented as $msil(C_m) = \sum_{p_i \in C_m} sil(p_i)$, where $-1 \leq msil(C_m) \leq 1$, and $msil(C_m) \to 1$ means the high quality of the cluster m. Based on the definition of silhouette values, we give **Algorithm 1** of choosing period cluster from a clustering result. Algorithm 1 shows that if the mean silhouette value of the overall clustering result is less than a pre-defined threshold value η, then the clustering result is unqualified. Feature vectors of points need to be re-clustered with adjusted parameters, e.g.,

ALGORITHM 1: Cluster quality validation

Input: (1) $V = \{vec_i | 1 \leq i \leq |CTS|\}$, where $vec_i = (\alpha^i, diff1_i, diff2_i)$
(2) A set of point clusters: $C_{CTS} = \{C_m | 1 \leq m \leq k\}$
(3) Threshold values η and ξ, $0 \leq \eta, \xi \leq 1$
Output: Period cluster C_{perid}
Calculate $sil(p_i)$ for $\forall p_i \in CTS$;

change the number of clusters. The last line indicates that the chosen period cluster is the one with highest mean silhouette values that is higher than a threshold ξ.

Step 3. Segmentation and annotation of periods. As mentioned in the previous section, a CTS can be divided into a series of periods by using the period points. Thus detecting a local anomaly in CTS means to identify an abnormal period or periods. In this section, we introduce a segmenting approach to extract the main and common features of each period. The extracted information will be used as classification features that are used for model learning and anomaly detection. In addition, signal annotations (e.g., '*Normal*' and '*Abnormal*') are attached to each period based on the original labels of the corresponding PTS. We will first give the concept of a summary of a period.

Definition 4.6. Given a CTS that has been separated into D periods, a **summary** of a period $pd_i = (v_{i_1}, \cdots, v_{i_m}), 1 \leq i \leq D$ is a vector $seg_i = (h_i^{min}, t_i^{min}, h_i^{max}, t_i^{max}, h_i^{mea}, p_i^{minmax}, p_i^l)$, where h_i^{min} is the amplitude value of the point having minimum amplitude in period i: $h_i^{min} = min\{v_{i_k}; 1 \leq k \leq m\}$; t_i^{min} is the time index of the point with minimum amplitude. If there are two points having the minimum amplitude, t_i^{min} is the time index of the first point. $h_i^{max} = max\{v_{i_k}\}$; t_i^{max} is the first point with maximum amplitude; $h_i^{mea} = \frac{1}{m}(\sum v_{i_k})$; $p_i^{minmax} = |t_i^{max} - t_i^{min}|$; $p_i^l = t_{i_m} - t_{i_1}$.

We represent the segmented CTS as $STS = \{seg_1, \cdots, seg_n\}$. Each period corresponds to an annotation ann indicating the state of the period. In this paper, we will only consider two states: $normal$ and $abnormal$. Therefore, a STS is always associated with a series of annotations $A_{STS} = \{ann_1, \cdots, ann_n\}$.

For the supervised pattern recognition model, the original PTS has a set of labels to indicate the states of the disjoint sub-sequences of PTS, which are represented as $Lbs = \{lb_{(1)}, \cdots, lb_{(w)}\}$, $\forall lb_{(r)} = \{'N'(Normal), 'Ab'(Abnormal)\}, 1 \leq r \leq w$. However, Lbs cannot be attached to the segmentations of the PTS directly because the periodic separation is independent from the labelling process. To determine the state of a segmentation, we introduce a logical-multiplying relation of two signals:

Rule 1. $ann = \otimes('Ab', 'N') = 'Ab'$ ***and*** $ann = \otimes('N', 'N') = 'N'$.

Assume a period covers a subsequence that is labelled by two signals, if there exists an abnormal behaviour in the subsequence, then based on rule 1, the behaviour of the segmentation of the period is abnormal; otherwise the period is a normal series. This label assignment rule can be extended to multiple labels: given a set of labels $Lbs = \{lb_1, \cdots, lb_r\}$, if $\exists lb_j = 'Ab', 1 \leq j \leq r$, the value of Lbs is $'Ab'$, represented as $lbs = \otimes(lb_1, \cdots, lb_r) = 'Ab'$; if $\forall lb_j = 'N', lbs = 'N'$.

ALGORITHM 2: Period annotation

Input: Period $pd_i = (v_{i1}, \cdots, v_{im}), 1 \leq i \leq n$;
A series of labels $Lbs = (lb_1, \cdots, lb_r)$;

Output: An annotated $pd_i^{'}$;

$t_i^1 = NULL$: the time of the 1^{st} annotation in the period;
$t_i^{end} = NULL$: the time of the last annotation in the period;
if $\exists lb_j$ that $t_{(i-1)1} \leq t_{j-1} \leq t_{(i-1)m} < t_{i1} \leq t_j \leq t_{im}$ **then**
    $t_i^1 = t_j$;
end
if $\exists lb_k$ & $t_{i1} \leq t_k \leq t_{im}$ & $t_{(i+1)1} \leq t_{k+1} \leq t_{(i+1)m}$ **then**
    $t_i^{end} = t_k$;
end
if $t_i^1 \neq NULL \parallel t_i^{end} \neq NULL$ **then**
    if $t_i^1 = NULL$ **then**
        $t_i^1 =' N'$
    end
    if $t_i^{end} = NULL$ **then**
        $t_i^{end} =' N'$
    end
    $Lbs = Lbs\{t_i^1, \cdots, t_i^{end}\}$;
    $lbs = \otimes(Lbs)$;
else
    $lbs = Lbs\{t_{i+1}^1\}$;
end

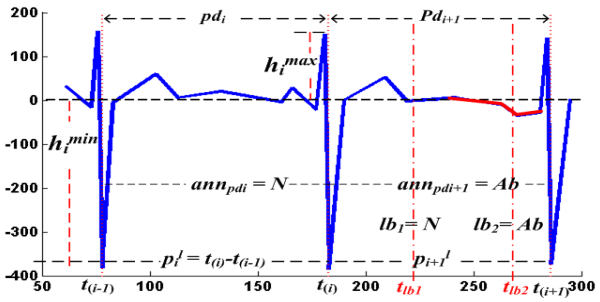

Fig. 5. Segmentation and annotation of two periods

According to the above discussion, the annotation of a period pd_i is determined by **Algorithm 2**.

Example 4.7. We present the segmentation and annotation of a period in Fig.5 to explain their processes more clearly. Fig.5 shows that pd_i does not involve any label and the first label in pd_{i+1} is $lb_1 = N$, so $lb_{pd_i} =' N'$. lb_2 is 'Ab', hence pd_{i+1} is annotated as 'Ab'.

4.2.3. Classification-based Anomaly Detection and Prediction: ADPC. From Definition 4.6, each period of a PTS is summarised by seven features of the period: $(h_i^{min}, t_i^{min}, h_i^{max}, t_i^{max}, h_i^{mea}, p_i^{minmax}, p_i^l)$. Using these seven features to abstract a period can significantly reduce the computational complexity in a classification process.

In the next section, we validate the proposed anomaly detection framework with various classification methods on the basis of different ECG datasets.

5. EXPERIMENTAL EVALUATION

Our experiments are conducted in four steps. The first step is to compress the raw ECG time series by utilizing the DP algorithm, and to represent each inflexion in the perceived CTS as a feature vector (see Definition 4.4). Secondly, the K-means++ clustering algorithm is applied to the series of feature vectors of the CTS, and the clustering result is validated by silhouette values. Based on the mean silhouette value of each cluster, a period cluster is chosen and the CTS is periodically separated to a set of consistent segments. Thirdly, each segment is summarised by the seven features (see Definition 4.6). Finally, a normal pattern of the time series is constructed and anomalies are detected by utilizing classification tools on the basis of the seven features.

We validate the proposed framework on the basis of eight ECG datasets [Goldberger et al. 2000a], which are summarised in Table II where 'V' represents Premature ventricular contraction, 'A': Atrial premature ventricular, and 'S': Supraventricular premature beat. Apart from the $aftdb$ dataset, each time series is separated into a series of subsequences that are labelled by the dataset provider. We give the number of abnormal subsequences ('#ofAbnor') and the number of normal subsequences ('#ofNor') of each time series in Table II.

Our experiment is conducted on a 32-bit Windows system, with 3.2GHz CPU and 4GB RAM. The ECG datasets are downloaded to a local machine using the WFDB toolbox [Silva and Moody 2014; Goldberger et al. 2000b] for 32-bit MATLAB. We use the 10-fold cross validation method to process the datasets.

The metrics used for evaluating the final anomaly classification results include:
(1) Accuracy (acc): $(TP + TN)$ / Number of all classified samples;
(2) Sensitivity (sen): TP / $(TP + FN)$;
(3) Specificity (spe): TN / $(FP + TN)$;
(4) Prevalence (pre): TP / Number of all samples.
(5) Fmeasure (fmea): $2 * \frac{precision*recall}{precision+recall}$, where $recall = sen$, $precision = \frac{TP}{TP+FP}$
TP = true positive, TN = true negative, FP = false positive, and FN = false negative.

Details of the experiments are illustrated in the following sections.

5.1. Inflexion Detection and Time Series Compression

At first, we design an experiment to detect the inflexions in a time series. The detected inflexions will be used as an approximation of the raw time series, and will be compressed by DP algorithm. We design this experiment based on the work of [Rosin 2003]. We assess the stability of the uncertainty detection and DP compression algorithms under the variations of the change of scale parameters and the perturbation of data. The former is measured by using a monotonicity index and the latter is quantified by a break-point stability index.

Table III. Decreasing monotonicity degree of six datasets in terms of the value of ϵ and λ

	ahadb	svdb	sddb	mitdb	mgh	aftdb
ϵ	100	100	100	100	100	100
λ	100	100	100	100	100	100

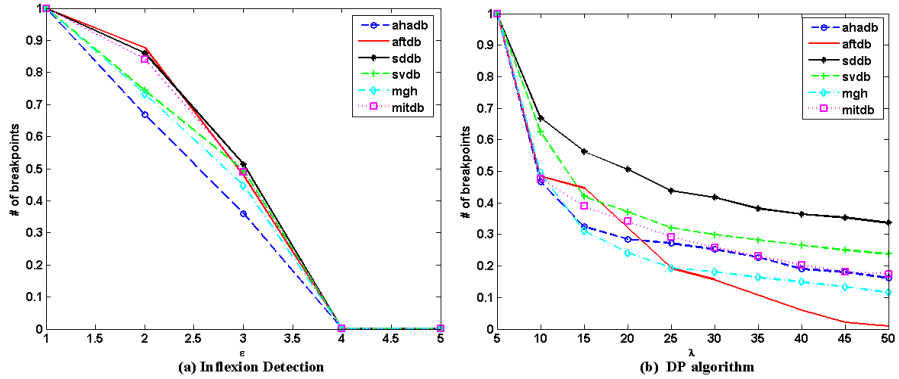

Fig. 6. Monotonically decreasing number of breakpoints in terms of ϵ for the inflexion detection procedure and λ for the DP algorithm

The monotonicity index is used to measure the monotonically decreasing or increasing trend of the number of break points when the values of scale parameters of a polygonal approximation algorithm are changed. For the inflexion detection algorithm and the DP algorithm, if the values of the scale parameters ϵ and λ are increasing, the number of the produced breakpoints of the time series will be decreasing, and vice versa. The decreasing monotonicity index is defined as $M_D = (1 - \frac{T_+}{T_-}) \times 100$, and the increasing monotonicity index is $M_I = (1 - \frac{T_-}{T_+}) \times 100$, where $T_- = -\sum_{\forall \Delta v_i < 0} \Delta v_i / h_i$, $T_+ = \sum_{\forall \Delta v_i > 0} \Delta v_i / h_i$, and $h_i = \frac{v_i + v_{i-1}}{2}$. Both of M_D and M_I are in the range $[0, 100]$, and their perfect scores are 100.

We test the decreasing monotonicity degrees for the datasets $ahadb$, $svdb$, $sddb$, $mitdb$, mgh, and $aftdb$ in terms of different values of ϵ for inflexion detection procedure and λ for DP algorithm. For the inflexion detection procedure, we set $\epsilon = 1, 2, 3, 4, 5$. Table III shows that the breakpoint numbers for the six datasets are perfectly decreasing in terms of the increasing ϵ, which can also be seen in Fig.6(a). For DP algorithm, we first fix $\epsilon = 1$, and detect inflexions of the six time series. Based on the detected inflexions, we set $\lambda = 5, 10, 15, 20, 25, 30, 35, 40, 45, 50$ to conduct DP compression. From Table III and Fig.6(b), we can see that the numbers of breakpoints are also 100% decreasing in terms of the increasing λ.

The break-point stability index is defined as the shifting degree of breakpoints when deleting increasing amounts from the beginning of a time series. We use the endpoint stability to test the breakpoint stability for fixed parameter settings : $\epsilon = 1$ for the inflexion detection and $\lambda = 10$ for the DP algorithm. The endpoint stability measurement is defined as $S = (1 - \frac{1}{m} \sum_d \sum_b \frac{s_b^d}{n_d l_d})$, where m is the level number of deletion, d is the dth level, s_b^d is the shifting pixels at breakpoint b, l_d is the length of the remaining time series and n_d is the number of breakpoints after the dth deletion. Table IV shows the deletion length of each running circle and the stability degree of each time series. For example, after inflexion detection, the sample number of $ahadb$ is 307350. We iteratively delete 10000 samples from the beginning of the remaining $ahadb$ time series, and

Table IV. Endpoint stability of six datasets and pertubations

	ahadb	svdb	sddb	mitdb	mgh	aftdb
Shifting length	10000	10000	10000	10000	10000	100
S	100	99.8988	99.9955	99.9725	99.9348	99.9351

conduct the DP algorithm based on the new time series. The positions of the identified breakpoints in each running circle are compared with the positions of the breakpoints identified in the whole $ahadb$. From Table IV, we can see that each time series is of high stability (i.e. values of S) when conducting the uncertainty detection procedure and the DP algorithm with fixed scale parameters.

5.2. Compressed Time Series Representation

From the above testing (see Fig.6), we can see that when $\epsilon \geq 4$, the number of detected inflexions of each time series is going to be 0. Based on Fig.6, we set $\epsilon = 1$ and $\lambda = 10$ for inflexion detection and time series compression. We then compare three methods of period point representation: (1) inflexions in CTS are represented by feature vectors (FV); (2) inflexions are represented by angles (Angle) of peak points [Huang et al. 2014]; (3) inflexions are represented by valley points (Valley) [an Tang et al. 2007]. Valley points are points in a PTS, which have values less than an upper bound value (represented as U). U is initially specified by users and will be updated as time evolves. The update procedure is defined as $U_b = \alpha(\sum_{i=1}^{N} V_i)/N$, where N is the number of past valley points and α is an outlier control factor that is determined and adjusted by experts. As stated by Tang et al.[an Tang et al. 2007], the best values of initial upper bound and α in ECG are $50mmHg$ and 1.1. The perceived feature vector sets, angle sets, and valley point sets are passed to the next step in which points are clustered and the period points of the CTS are identified. Each period is then segmented using the proposed segmentation method(see Definition 4.6). Finally, Linear Discriminant Analysis (LDA) and Naive Bayes(NB) classifiers are applied for sample classification and anomaly detection. Fig 7 shows the identified period points using the FV-based method for four datasets: $ltdb$, $sddb$, $svdb$ and $ahadb$. From Fig 7, we can see that for each dataset, the FV-based method successfully identifies a set of periodic points that can separate the CTS in a stable and consistent manner.

Table V presents the silhouette values of clustering the inflexions in the $CTSs$ of seven time series, where column 'mean' refers to the mean silhouette value of a dataset clustering, and the values in columns c(luster)1-6 are the mean silhouette values of each cluster after clustering a dataset. 'NAs' in the sixth column means that the inflexions in the corresponding datasets are clustered into five groups, which present the best clustering performance in this dataset. From Definition 4.5, we know that if the silhouette values in a cluster is close to 1, the cluster includes a set of points having similar patterns. On the other hand, if the silhouette values in a cluster are significantly different from each other or have negative values, the points in the cluster have very different patterns with each other or they are more close to the points in other clusters. Table V shows that for each of the seven datasets, the mean silhouette values of the overall clustering result and each of the individual clusters are higher than 0.4 ($\eta = 0.4$ in algorithm 1). The best silhouette value of an individual cluster in each dataset is close to or higher than 0.9 ($\xi = 0.8$ in Algorithm 1). In addition, for each dataset, we select the points in the cluster with highest silhouette value as the period points. For example, for dataset $ahadb$, points in cluster 4 are selected as period points.

Fig 8 presents the silhouette values of clustering the inflexions in the $CTSs$ of $mitdb$ and $ltdb$ time series. From this figure, we can see that for both the $mitdb$ and $ltdb$ datasets, FV-based clustering results in fewer negative silhouette values in all clus-

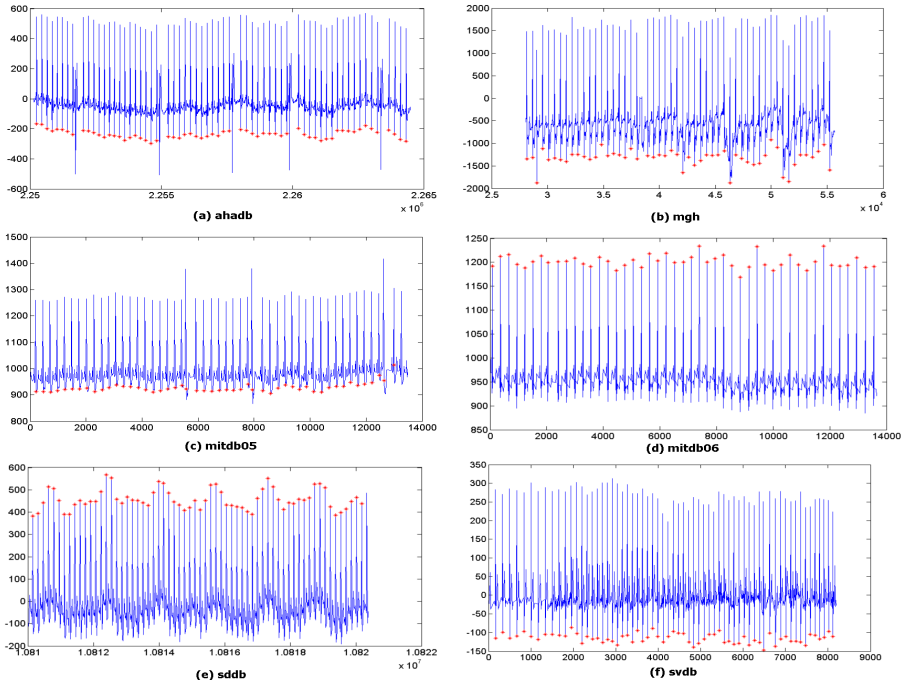

Fig. 7. Period point identification of four datasets based on feature vectors

Table V. Silhouette values of six datasets

Dataset	Silhouette values						
	mean	cluster1 (c1)	c2	c3	c4	c5	c6
ahadb	0.8253	0.4479	0.8502	0.9824	0.9891	0.9381	NA
svdb	0.6941	0.9792	0.6551	0.9703	0.5463	0.5729	0.959
sddb	0.772	0.6888	0.5787	0.965	0.9727	0.6971	0.7529
mitdb	0.9373	0.9877	0.7442	0.9898	0.9711	0.5854	0.3754
mitdb06	0.7339	0.7317	0.8998	0.609	0.8577	0.8669	NA
ltdb	0.9149	0.9164	0.8381	0.9739	0.9079	0.8975	NA
mgh	0.8253	0.4479	0.8502	0.9824	0.9891	0.9381	NA

ters, and he values in each cluster are more similar to each other compared with the angle-based clustering. We also come to a similar conclusion by examining their mean silhouette values. The mean silhouette values of FV-based clustering for $mitdb$ (corresponding to Fig.8(a)) is 0.9373, while the angle-based clustering (Fig.8(b)) is 0.7461; and the mean values for $ltdb$ are 0.9149 and 0.8155 (Fig.8(c) and Fig.8(d)) respectively.

Fig.9 compares the average classification performance on the basis of four datasets using four classifiers: LDA, NB, Decision tree (DT), and AdaBoost (Ada) with 100 ensemble members. From Fig.9, we can see that the classifiers based on the FV periodic separating method have the best performance in terms of the four datasets (i.e., the highest accuracy, sensitivity, f-measure, and prevalence). In the case of LDA and DT, the valley-based periodic separating method has the worst performance while in the cases of NB and Ada, valley-based methods perform better than angle-based methods.

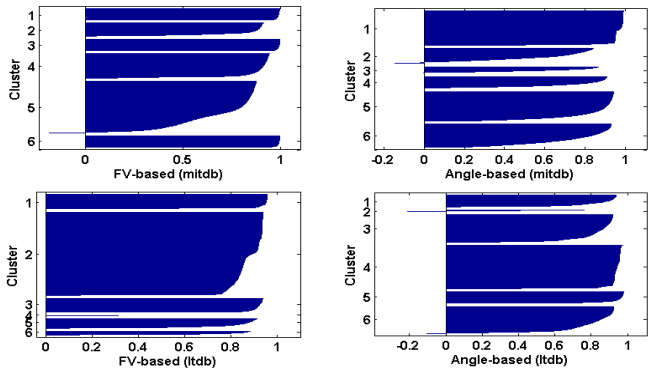

Fig. 8. Silhouette value comparison between the feature vector based clustering method (FV-based) and the angle-based clustering method for the $mitdb$ and $ltdb$ datasets

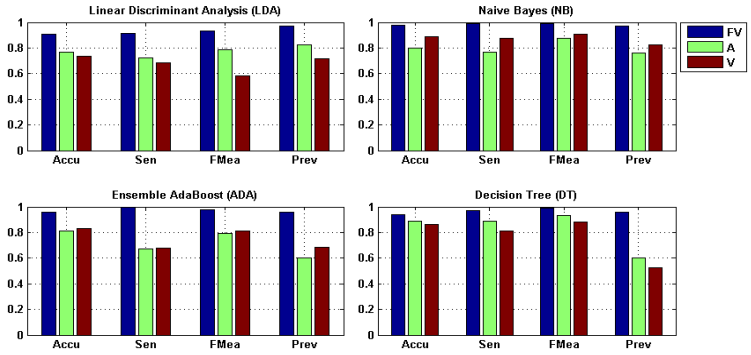

Fig. 9. Average performance comparison of four classifiers (LDA, NB, ADA, DT) based on feature vector based (FV), angle based (A) and valley point based (V) periodic separating methods

5.3. Evaluation of Classification Based on Summarized Features

This section describes the experimental design and the performance evaluation of classification based on the summarized features. This experiment is conducted on seven datasets: $ahadb$, $svdb$, $sddb$, $mitdb$, $mitdb06$, mgh, and $ltdb$. From the previous subsections, we know that the seven time series have been compressed and the period segmenting points have been identified (see Table V). The segments of each of the time series are classified by using three classification tools: Random Forest with 100 trees (RF), LDA and NB. We use matrices of acc, sen, spe, and pre to validate the classification performance.

The classification performance is shown in Fig.10, which compares the performance of classification methods LDA, NB and RF, based on datasets (a) *ahadb*, (b) *sddb*, (c) *mitdb*, (d) *mgh*, (e) *svdb*, and (f) *mitdb06*. From the figure, we can see that for all six datasets, the performances of NB and RF are better than the performance of LDA based on the selected features. The accuracy and sensitivity of NB and RF are higher than 80% for each of the datasets. Their prevalence values are over 90% for the first five datasets (a-e). However, we can also see that the feature values of LDA are always higher than the feature values of the other two methods.

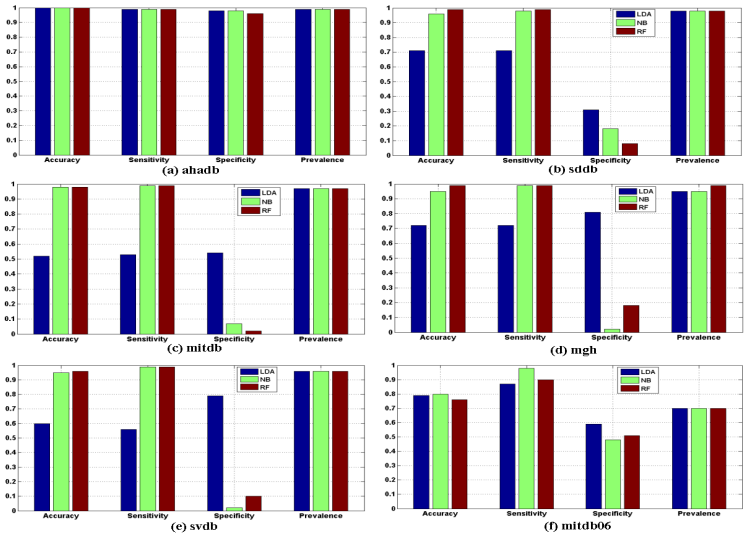

Fig. 10. Classification performance of six datasets based on the summarized features using classification methods of LDA, RF, and NB

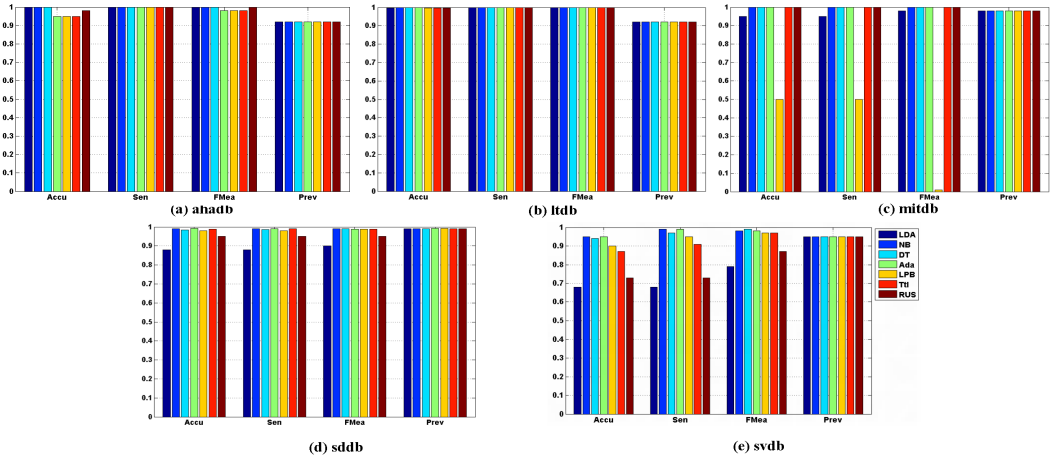

Fig. 11. Performance of seven classifiers (LDA, NB, DT, Ada, LPB, Ttl, and RUS) based on the proposed period identification and segmentation methods on five datasets ((a) ahadb, (b) ltdb, (c) mitdb, (d) sddb, and (e) svdb)

5.4. Performance Evaluation of Other Classification Methods Based on Summarized Features

In this section, we design an experiment to evaluate the performance of the proposed time series segmentation method. Experimental results on the basis of five datasets (i.e.,$mitdb$, $ltdb$, $ahadb$, $sddb$ and $svdb$) are presented in this section. We carry out the experiment by the following steps. First, the raw time series are compressed by DP algorithm and periodically separated by feature vector based period identification method. Second, each period is summarized by the proposed period summary method (see Definition 4.7) and is annotated by the annotation process(see Section 4.3). The classification methods used in this experiment include LDA, NB, DT, and a set of ensemble

methods: AdaBoost (Ada), LPBoost (LPB), TotalBoost (Ttl), and RUSBoost (RUS). The classification performance is validated by five benchmarks: acc, sen, $fmea$, and $prev$.

Fig.11 shows the evaluated results of the classifier performance based on the proposed period identification and segmentation method. From Fig.11, we can see that the accuracy values of classification based on the 5 datasets are over 90%, except the cases of LPB with $mitdb$, LDA with $sddb$, LDA with $svdb$, and RUS with $svdb$. Some of them are of more than 98% accuracy. The sensitivity of classification based on the datasets of $ahadb$, $ltdb$, and $mitdb$ are closing to 100%. The sensitivity based on the datasets of $sddb$ and $svdb$ are over 85%. The f-measure rates of classification based on $ahadb$, $ltdb$, $mitdb$, and $sddb$ are higher than 95%. The f-measure rates of RUS and LDA based on $mitdb$ and $svdb$ are less than 80%, but the f-measure of other classifiers based on these two datasets are all higher than 80%, and some of them are closing to 100%. The prevalence rates of classification on the basis of the five datasets are over 90%.

6. CONCLUSIONS

In this paper, we have introduced a framework of detecting anomalies in uncertain pseudo periodic time series. We formally define pseudo periodic time series (PTS) and identified three types of anomalies that may occur in a PTS. We focused on local anomaly detection in PTS by using classification tools. The uncertainties in a PTS are pre-processed by an inflexion detecting procedure. By conducting DP-based time series compression and feature summarization of each segment, the proposed approach significantly improves the time efficiency of time series processing and reduces the storage space of the data streams. One problem of the proposed framework is that the silhouette coefficient based clustering evaluation is a time consuming process. Though the compressed time series contains much fewer data points than the raw time series, it is necessary to develop a more efficient evaluation approach to find the optimal clusters of data stream inflexions. In the future, we are going to find a more time efficient way to recognize the patterns of a PTS. In addition, we will do more testing based on other datasets to further validate the performance of the method. Correcting false-detected inflexions and detecting global anomalies in an uncertain PTS will be the main target of our next research work.
