**Abstract**

Bacterial infections in healthcare settings are a frequent accompaniment to both routine procedures such as catheterization and surgical site interventions. Their impact is becoming even more marked as the numbers of medical devices that are used to manage chronic health conditions and improve quality of life increases. The resistance of pathogens to multiple antibiotics is also increasing, adding an additional layer of complexity to the problems of employing safe and effective medical procedures. One approach to reducing the rate of infections associated with implanted and indwelling medical devices is the use of polymers that resist the formation of bacterial biofilms. To significantly accelerate the discovery of such materials, we show how state of the art machine learning methods can generate quantitative predictions for the attachment of multiple pathogens to a large library of polymers in a single model for the first time. Such models facilitate design of polymers with very low pathogen attachment across different bacterial species that will be candidate materials for implantable or indwelling medical devices such as urinary catheters, cochlear implants and pacemakers.

## Introduction

Bacterial infections are a large and re-emerging global healthcare issue because of ageing populations, the evolution of multi- and pan- antibiotic resistant pathogens, increasing numbers of immunocompromised patients, and developments in and use of medical devices. Immune responses abate with ageing, and concurrent medical conditions mean that hospitalizations are increasing and nosocomial infections more prevalent.<sup>1-2</sup> Antibiotic resistance is a major global healthcare challenge, and the increased use of implantable and indwelling medical devices is hampered by the risk of bacterial infections, especially by multi-antibiotic resistant pathogens.<sup>3-4</sup> Additionally, wound infections, traumatic burns, suppressed immune responses due to HIV infection or organ transplantation, and increased survival of patients with chronic serious conditions such as cystic fibrosis and diabetes add to the overall burden of infection.

Health care-associated infections affect around 4.1 million per year in Europe and around 1.7 million patients in the USA, according to World Health Organization.<sup>5</sup> Bacterial colonization of, and subsequent biofilm formation on, medical devices are particularly problematic given the rapidly growing number of patients requiring for example, catheterization, stents, cochlear implants, pacemakers and other major and minor surgical interventions.<sup>1, 3-4</sup> New materials are needed for medical device applications that prevent infection by broadly resisting attachment and subsequent formation of antibiotic tolerant biofilms by diverse pathogens. These materials have advantages over those that incorporate antibiotics including: efficacy against strains resistant to incorporated antibiotics; low antibiotic resistance pressure; enduring performance because the active components cannot leach away. Consequently, a substantial amount of research and development is now being conducted into identifying new types of materials, chiefly polymers, that prevent bacterial colonization and hence biofilm development. The current status has been

1  
2  
3 summarized in recent reviews.<sup>6-12</sup> In spite of some promising outcomes, given the immense size  
4 of materials space, it is essential that automated and high throughput materials synthesis and  
5 assessment methods be adopted to identify suitable materials quickly and allow their use in  
6 medical devices.<sup>13</sup>  
7  
8  
9  
10  
11

12 Clearly it would be ideal if we fully understood the diverse sensing and signaling mechanisms  
13 that bacteria employ to determine whether they are near or on a surface, and whether that surface  
14 is suitable for attachment and biofilm formation. Such knowledge would allow the direct,  
15 rational design of surfaces that do not support bacterial colonization. As recent articles on this  
16 topic indicate,<sup>14-15</sup> mechanistic information is still far from complete. Pathogens use  
17 sophisticated, diverse strategies to colonize a surface are that involve multiple surface  
18 appendages and macromolecules including pili, flagellar, proteins and exopolysaccharides.<sup>14, 16-18</sup>  
19 Attachment can be reversible or irreversible and mature biofilms disperse, releasing bacterial  
20 cells to search for new attachment sites.<sup>19</sup> Pathogen interactions are modulated by surface  
21 physicochemical interactions,<sup>20</sup> and involve substantial changes in gene expression through an  
22 integrated network of bacterial sensing and signalling systems that operate at transcriptional and  
23 post-transcriptional levels and involve e.g. multiple two-component sensor regulators,  
24 mechanosensors, quorum sensing systems, riboregulatory networks and second messenger  
25 molecules (e.g. cyclic diguanylate).<sup>14-18, 21</sup> Consequently, we are not yet at the point where  
26 sufficient information is available to permit the rational design of low attachment surfaces as an  
27 effective and reliable strategy for new materials discovery. High throughput experimentation is a  
28 practical alternative to rational design in the majority of situations where the primary aim is to  
29 discover translatable materials to solve real clinical problems. However, high throughput

7  
8 An experimental high throughput materials discovery campaign was undertaken to identify  
9 new acrylate polymers with reduced attachment and biofilm formation, initially using a single  
10 strain belonging to each of three major pathogen species, but subsequently using multiple clinical  
11 isolates.<sup>22</sup> *Pseudomonas aeruginosa* (PA), *Staphylococcus aureus* (SA), and uropathogenic  
12 *Escherichia coli* (UPEC) attachment was compared with existing commercial medical device  
13 materials such as silicone rubber and silver-containing hydrogel coatings. Acrylate polymers  
14 presented in a microarray format (see Figure 1) were screened to identify promising materials  
15 that minimized bacterial attachment and biofilm formation *in vitro* and in an *in vivo* foreign body  
16 infection model.<sup>22-23</sup> Some of these materials are now undergoing regulatory approval for use as  
17 urinary catheter coatings.

30  
31 Data-driven computational modelling methods that extract useful information from large data  
32 sets are an important adjunct to accelerated synthesis and testing technologies. The experiments  
33 generated large, information rich data sets derived from many hundreds of polymers and more  
34 than 20,000 assays. These data were used in the current work to extract useful information on  
35 relationships between polymer surface chemistry and bacterial attachment, and to predict  
36 attachment of multiple pathogens on materials not used to generate the models. We previously  
37 employed a sparse feature selection and a Bayesian Regularized Artificial Neural Network  
38 (BRANN) approach to generate quantitative and predictive models of the attachment of each of  
39 the three pathogens to diverse acrylate materials.<sup>24</sup> These has important advantages over other  
40 modelling techniques. They are very resistant overtraining and overfitting, as they automatically  
41 generate sparse models and select sparse sets of relevant molecular features with optimum

predictive capabilities. Although linear models of the relationships between surface chemistry and bacterial attachment reported by Hook et al. showed some predictive abilities for pathogen attachment, nonlinear neural network-based models are often significantly more robust and predictive and were used in the current study. Sanni et al.<sup>25</sup> also results of reported a study that used the highest performing (lowest bacterial attachment) subset of the monomers reported in the Hook et al. study and used here, correlating bacterial cell attachment with a composite parameter composed of contributions from the lipophilicity and molecular flexibility of the monomer units.

There is often a lack of clarity, even within the QSPR modelling community, on the two main purposes of machine learning and other statistical methods that model the relationships between the properties of molecules or materials and their biological effects. One aim is to understand the details of the molecular interactions and mechanisms underlying the biological phenomena being modelled. The other aim, now dominant in drug discovery and materials design, is to be able to predict the biological response of materials yet to be synthesized, allowing very large virtual libraries of synthetically feasible materials to be prioritized for subsequent synthesis and testing and discovering useful materials more quickly. This aim is driven by the need to translate into real medical applications novel materials with hitherto inaccessible properties. It is this aim that our current research is pursuing. These disparate but synergistic uses of models have been elucidated recently by Winkler and Fujita.<sup>26</sup> QSPR models can also be used fitness functions in evolutionary processes that allow materials to be evolved towards one of more desirable properties.<sup>27</sup>

Given our previous success in generating computational models capable of making quantitative predictions of attachment of single pathogen to a polymer library, here we report for the first time a single computational model that can predict the polymer attachment of multiple

1  
2  
3 pathogens *simultaneously*. It should be noted that these experiments and models predict the  
4 attachment of single pathogen strains to polymers not mixtures of different pathogens. The  
5 approach we have taken is similar to multitask networks<sup>28-29</sup>, which have proven to be successful  
6 in predicting the biological activities of small molecules against several targets. Multitask  
7 models potentially have wide applicability in materials science and medicine as they can identify  
8 materials with low attachment for a range of important pathogens and strains, rather than for a  
9 single pathogen strain. We compare the performance of the multi-pathogen model to that of the  
10 three, single pathogen strain computational models. Such models may also lead to general rules  
11 that relate low attachment to specific types of surface chemistry of polymers. A similar  
12 computational approach is used in small molecule drug discovery to find alternative drug  
13 targets.<sup>30</sup>

## 28 **Experimental Methods**

### 31 *Polymer library and pathogen attachment data.*

32  
33 Data for pathogen attachment to a polymer library containing 496 acrylate copolymers and  
34 homopolymers were obtained from Hook et al.<sup>23</sup> Acrylate polymers was used because of the  
35 robustness and reliability of this type of polymer when used in the microarray format in our  
36 hands.<sup>23-24, 31-33</sup> Homo- and copolymers were generated by combinatorial reaction of different  
37 ratios of each monomer prior to UV-initiated polymerization. The nomenclature adopted for the  
38 copolymers is as follows: 1A(30%) means the polymer is composed of 70% of monomer 1 and  
39 30% of monomer A by volume.

40  
41  
42 The bacterial attachment was measured using the fluorescence of bacteria transformed with  
43 green fluorescent protein. The brightness of the green fluorescence was proportional to the  
44 number of bacteria on the spot. As some polymers show a degree of autofluorescence, we

4  
5 media  
6

$$7 \quad F = F_{\text{polymer + bacteria}} - F_{\text{polymer}} \quad (1)$$

8  
9  
10 As the fluorescence spanned several orders of magnitude, we modelled the logarithm of the  
11  
12 fluorescence, logF.  
13

14  
15 Two additional new polymer arrays were used to validate blind predictions of the models, the  
16  
17 gold standard for assessing the utility of computational models.<sup>34</sup> These arrays were constructed  
18  
19 as described previously by Hook et al. using the monomers and proportions shown in Figures S6  
20  
21 and S7 and Tables S6 and S7. Measurements of pathogen attachment were obtained using the  
22  
23 same bacterial strains, but transformed to express mCherry protein instead of GFP. This change  
24  
25 in protocol was made to minimize problems with autofluorescence of polymers and to improve  
26  
27 the signal-to-noise ratio and lower detection limits. However, this meant that a direct quantitative  
28  
29 comparison between the bacterial attachment predictions of the models for GFP-transformed  
30  
31 bacteria and those with bacteria expressing mCherry could not be made. For these validation  
32  
33 experiments the following screening protocol was adopted. The fluorescently-tagged bacteria  
34  
35 were grown for 12 h in LB (Luria-Bertani, Oxoid, UK) and used to inoculate RPMI-1640  
36  
37 defined medium ( $OD_{600} = 0.01$ ) containing the microarray slides. These were incubated at 37 °C  
38  
39 with shaking at 60 rpm for 72 h, the slides were removed and washed with phosphate buffered  
40  
41 saline (PBS, 15 mL) at room temperature three times for 5 min each, then rinsed with distilled  
42  
43 H<sub>2</sub>O and air dried. Fluorescence was measured with GenePix Autoloader 4200AL scanner, using  
44  
45 red laser 635nm and red emission filter. The data were screened as described above before  
46  
47 modelling and are summarized in Supplementary tables S6 and S7.

29

30 The analyses also required the removal of polymers having logF values below 5.6, the  
31 detection limit of the pathogen attachment assay, as we did not have information on what their  
32 actual fluorescence/attachment values were. It was also necessary to remove a few model  
33 outliers, a process that must be done carefully and objectively. Polymers with low fluorescence  
34 values that were  $<2.5\sigma$  of the background fluorescence were removed. These two steps  
35 eliminated 89 polymers from the PA data set, 18 from the SA data set and 409 from the UPEC  
36 data set. Four additional outliers were identified from the models. Polymers 1A(30%), 5F(15%),  
37 9D(15%) for the PA attachment model, and 5D(10%) for the SA attachment model had  
38 fluorescence values inconsistent with fluorescence of copolymers with similar compositions and  
39 were poorly predicted by the models.

identities and structures of the monomers used to generate the additional smaller and larger polymer arrays used to valid model predictions are summarized in Supplementary Figure S2 and S3.

**Figure 1.** Schematic of the processes employed in the micro array fabrication, pathogen screening, modelling of data, and prediction of pathogen attachment for new polymers.

### *Quantitative modelling*

Data sets were partitioned into training and test sets containing 80% and 20% of data points respectively. The splitting was done by using k-means clustering (generating k clusters related by descriptor similarity and choosing the cluster mean for the test set). This ensures that the test set spans the same range of descriptors and attachment levels as the training set so that predictions outside of the domain of the models do not occur. It also ensures reproducibility of results for others wishing to replicate our work. The PA attachment data set contained 404 polymers after removal of data points below the detection threshold and outliers. The data was divided into a training set of 323 polymers and a test set of 81 polymers. The SA attachment data set consisted of 477 points for modelling (after statistical assessment), split into 382 polymers in the training

1  
2  
3 set and 95 points in the test set. The protocol for measuring attachment of UPEC was different to  
4 that for the other two pathogens, as artificial urine was added to the culturing protocol to  
5 simulated the service environments that urinary catheters will encounter. This increased the  
6 variance in the measured bacterial fluorescence and resulted in a lower degree of attachment of  
7 UPEC to the polymers compared to that for SA and PA. UPEC also forms weaker adhering  
8 biofilms compared to PA and SA. Consequently, the UPEC data set only contain 87 polymers  
9 after omitting those below the detection limit (the majority), with experimental artefacts, or with  
10 unusually high variability in replicates. This data set was partitioned into 70 points for the  
11 training set and 17 for test set. After outlier removal and polymers with fluorescence below the  
12 detection limit, the resulting 968 multi-pathogen attachment polymer data set was split to a  
13 training set of 774 points and a test set of 194 points.

59  
60  
Molecular descriptors were calculated from the Dragon 7.01 package using SMILES strings to  
present the structures of monomers.<sup>35</sup> We generated 3839 constitutional, structural, and  
physicochemical descriptors that depended only on 2D structures. We and others<sup>36-38</sup> have shown  
that consideration of monomer or small oligomer structures alone can often provide good  
descriptions of polymer performance without consideration of other structural properties such as  
molecular weight, polydispersity, degree of branching copolymer block size, etc. Copolymer  
descriptors were calculated as a linear combination of monomer descriptors weighted by the  
proportion of each monomer in the copolymer.<sup>24</sup> Highly correlated descriptors ( $r^2 > 0.95$ ), and  
those with low variance in the data set were removed, to provide 1640 final descriptors. The  
most relevant descriptors were identified by multiple linear regression with expectation  
maximization (MLREM), an extremely sparse method of identifying features.<sup>39</sup> The sparsity was

1  
2  
3 adjusted by a parameter,  $\beta$ , to obtain a model with the lowest standard error of prediction (SEP)  
4  
5 for all three pathogens. This resulted in a set of descriptors shown in the table S1.  
6  
7

8 We have also used experimental time-of-flight secondary ion mass spectrum (ToF-SIMS) ion  
9 peaks derived from analysis of the surfaces of the polymer spots in the library as descriptors.  
10 These data were also obtained from Hook et al. and contained surface characterization of one  
11 spot from the six replicates.<sup>23</sup> The assignment of the identities of the peak ions and association  
12 with the polymer structures is described by Hook and Scurr.<sup>32</sup> The water contact area (WCA), a  
13 measure of surface polarity, was also measured in this paper and employed here as an  
14 experimental descriptor. Experimental data used for modelling are shown in Table S3.  
15  
16  
17  
18  
19  
20  
21  
22  
23

24 The multi-pathogen models were generated from a data set that combined all three pathogen  
25 attachment data sets, using an indicator variable as a descriptor to distinguish between the  
26 presence (1) or absence (0) of a specific pathogen. A Bayesian regularized Neural Network with  
27 Gaussian prior (BRANNGP) was used to generate the pathogen attachment models.<sup>40</sup> The neural  
28 network consisted of one input, one hidden and one output layer. The number of nodes in the  
29 hidden layer was varied from 2 to 10. However, previous reports<sup>41</sup> have shown that less than five  
30 hidden layer nodes are sufficient in almost all cases, and that specifying larger numbers of nodes  
31 results in almost identical models because of the Bayesian regularization.<sup>41</sup> The best model for  
32 each case was identified as the one with the lowest test set standard error of prediction (SEP), as  
33 is best practice.<sup>42</sup> However the standard error of estimation (SEE) for the training set prediction,  
34 and the  $r^2$  value for the training and test set predictions were also reported.  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47  
48

49 To ensure that the neural network was not biased by the order in which the data were presented  
50 during training, we shuffled the order of the rows. Shuffling of the data order has essentially no  
51 effect on the quality of the modelled generated. We also checked for overfitting (something  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Bayesian regularized neural networks are relatively immune to)<sup>41</sup> or chance correlations by  
4 randomly redistributed only the y-values. This gave models with  $r^2$  values very close to zero, as  
5 would be expected.  
6  
7  
8

9  
10 As described above, the predictions of pathogen adhesion of two new polymer libraries were  
11 complicated by a change in experimental protocols after generating, measuring, and modelling  
12 the data using GFP-modified bacteria. Pathogens genetically modified to express the mCherry  
13 fluorescent protein were used to check the prediction of the models for a new polymer array  
14 containing homo- and copolymers. This prevented a direct, quantitative validation of model  
15 predictions. The logarithm of the mCherry intensities were autoscaled (normalized) and three  
16 classes (low, medium, and high attachment) defined for each normalized set of data by  
17 inspection of the distributions in the histograms (see Supporting Figure S4). Truth tables were  
18 generated from the class membership of attachment of PA and UPEC to each polymer in the  
19 array.

## 32 33 34 35 36 **Results**

37  
38 The attachment of each of *P. aeruginosa* (PA), *S. aureus* (SA), and uropathogenic *E. coli*  
39 (UPEC) to the polymer microarray was modelled using two classes of descriptors:  
40 experimentally measured time of flight secondary ion mass spectrometry (ToF-SIMS) peak  
41 intensities and water contact angles (WCA); and computed molecular descriptors (from  
42 DRAGON)<sup>35</sup>. These descriptors describe the surface chemistry of the polymer spots on the arrays.  
43 Whilst WCA has been found to be a poor predictor of bacterial attachment across diverse  
44 libraries when used alone,<sup>23</sup> we wanted to investigate its utility when combined with the  
45 molecularly rich information from ToF-SIMS experiments.<sup>43</sup>

2  
3 Individual models predicting the attachment of each pathogen to the same polymer library  
4 were reported by Epa et al. using computed molecular descriptors specifically chosen to be  
5 chemically interpretable.<sup>24</sup> The aim of this prior work was to generate models that provided  
6 some insight into the relationship between surface chemistry and pathogen attachment, as well as  
7 making quantitative prediction of bacterial attachment of new materials. More arcane molecular  
8 descriptors generally provide improved predictive power at the expense of loss of chemical  
9 interpretability. Given the added complexity of modelling surface chemistry-polymer  
10 attachments relationships for several pathogens simultaneously, in this work we chose  
11 descriptors solely for their ability to generate the most accurate predictions of pathogen  
12 attachment. We employed indicator variable descriptors to allow the entire set of pathogen  
13 attachment data to be used to train multi-pathogen attachment models that predict the  
14 performance of polymer libraries for all three pathogens (see Methods).

30 Here we compare the performance of multi-pathogen attachment models with those that  
31 predict attachment of single pathogens. We reiterate, these experiments and models predict the  
32 attachment of single pathogen strains to polymers not coincident mixtures of pathogens, as  
33 often occur in infections. Model performance was assessed by the ability of each model to  
34 recapitulate the attachment performance of polymers in a test set not used to train the models.  
35 We also compared the performance of experimental ion peak and water contact angle  
36 descriptors with computed molecular descriptors for single and multi-pathogen attachment  
37 models, to assess whether the extra effort involved in ToF-SIMS experiments was justified by  
38 higher model accuracy or interpretability.

#### 50 *Pathogen attachment models based on computed molecular descriptors*

51 The results of modelling the attachment of the three individual pathogens and the attachment  
52 of all three pathogens simultaneously to the polymer library are summarized in Table 1. These  
53  
54  
55  
56  
57  
58  
59  
60

models were generated by a Bayesian neural network (BRANN), and a linear multiple regression model (MLR) was also included for comparison. Clearly, the BRANN multi-pathogen model had significantly lower standard error of prediction (SEP) than the linear model so predicted the attachment to polymers in the test set more accurately (the  $r^2$  was also higher than the linear model). This is consistent with earlier studies of models predicting each pathogen separately.<sup>23-24</sup>

**Table 1.** Statistics of pathogen attachment neural network (BRANN) models based on molecular descriptors.  $N_{\text{eff}}$  is the number of effective adjustable weights, and  $N_{\text{des}}$  is the number of descriptors employed,  $N_{\text{hidden}}$  is the number of nodes in the hidden layer, SEE is the standard error of estimation, SEP is the standard error of prediction and  $r^2$  is the squared correlation coefficient of the predictions

| Model                       | $N_{\text{hidden}}$ | $N_{\text{eff}}$ | $N_{\text{des}}$ | Training set |       | Test set |       |

#### *Multi-pathogen model*

The best multi-pathogen attachment model was generated by a BRANN neural network model that employed 7 neurons in the hidden layer and 41 descriptors. The training set standard error of estimation (SEE) and test set standard error or prediction (SEP) values were 0.16 and 0.19 logF respectively for this model. The training and test set predictions had  $r^2$  values of 0.86 and 0.81,

1  
2  
3 indicating a high level of statistical significance and showing that the model was robust and  
4  
5 strongly predictive. Figure 2 illustrates the performance of the multi-pathogen model in

The linear MLR multi-pathogen attachment model was also statistically significant ( $r^2 \sim > 0.5$ , Table 2)<sup>44</sup> but the standard errors of prediction were larger (0.28 logF) than the nonlinear BRANN model (0.22 logF). The linear models were derived to elucidate the likely contributions of the descriptors to the models. The contributions of the computed molecular descriptors to the multi-pathogen model are summarized in Figure 3. The main purpose of this and related figures in the paper is to show which descriptors make positive or negative contributions to the

attachment of one or more pathogens, to provide a qualitative measure of the size of the contribution, and to make inferences of the role of surface chemistry where possible.

**Figure 3.** The weights of the descriptors in the linear multi-pathogen attachment model. The error bars represent the standard errors in the parameter estimations from the MLR model. See Supplementary Table S2 for an explanation of these descriptors and Discussion for the relevance to the model.

### *Single pathogen strain models*

Models relating pathogen attachment to surface chemistry were also generated for each pathogen separately. The model that best predicted PA attachment to polymers in the test set was derived using a neural network with 8 nodes in the hidden layer and used 30 descriptors. The training set SEE was 0.17 logF and  $r^2$  was 0.88, while the test set had an SEP of 0.17 logF and an  $r^2$  of 0.87. This suggests that the model was not overtrained and was quite robust. The SA attachment model had a training set SEE of 0.12 and a test set SEP of 0.14, and an  $r^2$  of 0.87 and 0.78 for predictions of attachment to polymers in the training and test sets respectively.

Despite the smaller data set size of the UPEC attachment study, a statistically valid and predictive model was obtained. The model used two neurons in hidden layer and 18 descriptors. The training and test set SEE and SEP values were 0.30 and 0.24 respectively, and the  $r^2$  for training set was 0.78 and for test set 0.94.

The graphs showing the correlations between the measured and predicted attachment for the individual pathogen models employing computed molecular descriptors are shown in Supplementary Figure S5.

#### *Pathogen attachment models based on ToF-SIMS ion peak descriptors*

Experimentally measured ToF-SIMS ion peaks and water contact angles (WCA) were also used as descriptors in the pathogen attachment models to assess their efficiency relative to the computed descriptors. The results of modelling the three individual pathogen data sets, and the combined multi-pathogen data sets with the experimental ToF-SIMS analysis and WCA data are summarized in Table 2. A linear MLR attachment model for multiple pathogens is included for comparison and to allow the contributions of ion peaks to the model to be evaluated.

**Table 2.** Statistics of pathogen attachment BRANN models based on ToF-SIMS molecular ion peaks and WCA values. See Supplementary Table S3 for ToF-SIMS descriptors used in the models

### *Multi-pathogen model*

As with the pathogen attachment model generated using computed molecular descriptors, the best performing attachment model employed a neural network (BRANN) with 5 neurons in the hidden layer and 79 descriptors. This model contained more effective weights but fewer descriptors than the same model using computed molecular descriptors. The training and test sets were predicted with good accuracy, with SEE and SEP values of 0.12 and 0.21 logF and  $r^2$  values of 0.76 and 0.74 respectively. Values of  $r^2$  above 0.7 shows that it is possible to generate a good combined model for the attachment of all three pathogens to the polymer library using data obtained from experimental techniques: ToF-SIMS, and WCA<sup>33</sup>. Figure 4 illustrates the performance of this multi-pathogen model in predicting the attachment of bacteria to the polymer library.

**Figure 4.** Measured and predicted attachment (estimated using the log of the GFP fluorescence, logF) of the multi-pathogen attachment model employing ToF-SIMS ion peak features and WCA from experiments as descriptors.

As with the linear multi-pathogen attachment model based on computed molecular descriptors, the experimental descriptors also generated a linear (MLR) model of multi-pathogen attachment of lower statistical significance ( $r^2 > 0.5$ , Table 2).<sup>44</sup> The standard error of prediction was larger (0.33 logF) than the nonlinear model (0.21 logF) and larger than that of linear multi-pathogen attachment model using computed molecular descriptors (0.28 logF). The contributions of the experimental descriptors to the linear model are summarized in Figure 5.

**Figure 5.** The weights of the descriptors in the linear multi-pathogen attachment model (different scales for the ToF-SIMS ion peaks, WCA, and the indicator variables for the three pathogens). The error bars represent the standard errors in the parameter estimations from the MLR model.

#### *Single pathogen strain models*

The best PA attachment model was obtained using a neural network containing 6 neurons in the hidden layer and 57 descriptors. The training and test sets were well predicted by this model, with SEE and SEP values of 0.14 and 0.22 logF and  $r^2$  values of 0.92 and 0.81 for training and

1  
2  
3 test sets respectively. The number of descriptors in the model is higher than in the other bacterial  
4 attachment models for SA and UPEC. The optimal SA attachment model was obtained from a  
5 BRANN model that used 8 neurons in the hidden layer and 19 descriptors. Again, the training  
6 and test set attachment was well predicted by the model, with SEE and SEP values of 0.11 and  
7 0.14 logF for training and test sets. The corresponding  $r^2$  values for these predictions were 0.88  
8 for the training set and 0.84 for the test set. The low standard errors, high  $r^2$  values, and the  
9 similarity in the prediction efficacy of training and test set data show that this model of SA  
10 attachment to the polymer library using experimental features is robust and predictive. The  
11 quality of the models is similar to those reported previously by Epa et al.,<sup>24</sup> which had an  
12 SEP=0.12 logF and  $r^2=0.85$  for the test set. The most predictive UPEC attachment model for the  
13 polymer library was obtained also using a neural network with 2 neurons in the hidden layer and  
14 10 descriptors. This model predicted attachment of UPEC with SEE and SEP values of 0.24 and  
15 the  $r^2$  values of 0.87 and 0.84 for training and test sets. The relatively small number of  
16 experimental descriptors and excellent model metrics show that there are few key molecular  
17 features important for UPEC attachment to the polymer surface. The model SEE and SEP values  
18 of 0.24 are significantly better than those reported by Epa, (0.43 and 0.48) presumably because  
19 the descriptors employed were more efficient than the chemically interpretable set used in the  
20 earlier study. In our study,  $r^2$  was higher for training set 0.87 vs 0.58 in Epa et al.'s model, while  
21  $r^2$  for test set was a slightly lower at 0.84 versus 0.73 in the Epa et al. study. However, as we  
22 have shown previously, the standard errors are a more robust measure of model predictivity than  
23 the  $r^2$  values.<sup>42</sup>

The graphs showing the correlations between the measured and predicted attachment for the individual pathogen models employing experimental descriptors are shown in Supplementary Figure S6.

## Discussion

We would first like to clarify that the term multi-pathogen should be not be confused with the term polymicrobial, which describes a situation where a number of bacterial species and strains coexist (common in many infections). By multi-pathogen, we mean we have tested one bacterial species and strain at a time. We have not performed experiments where we mix several strains together and examine their collective behaviour.

### *Single versus multi-pathogen models*

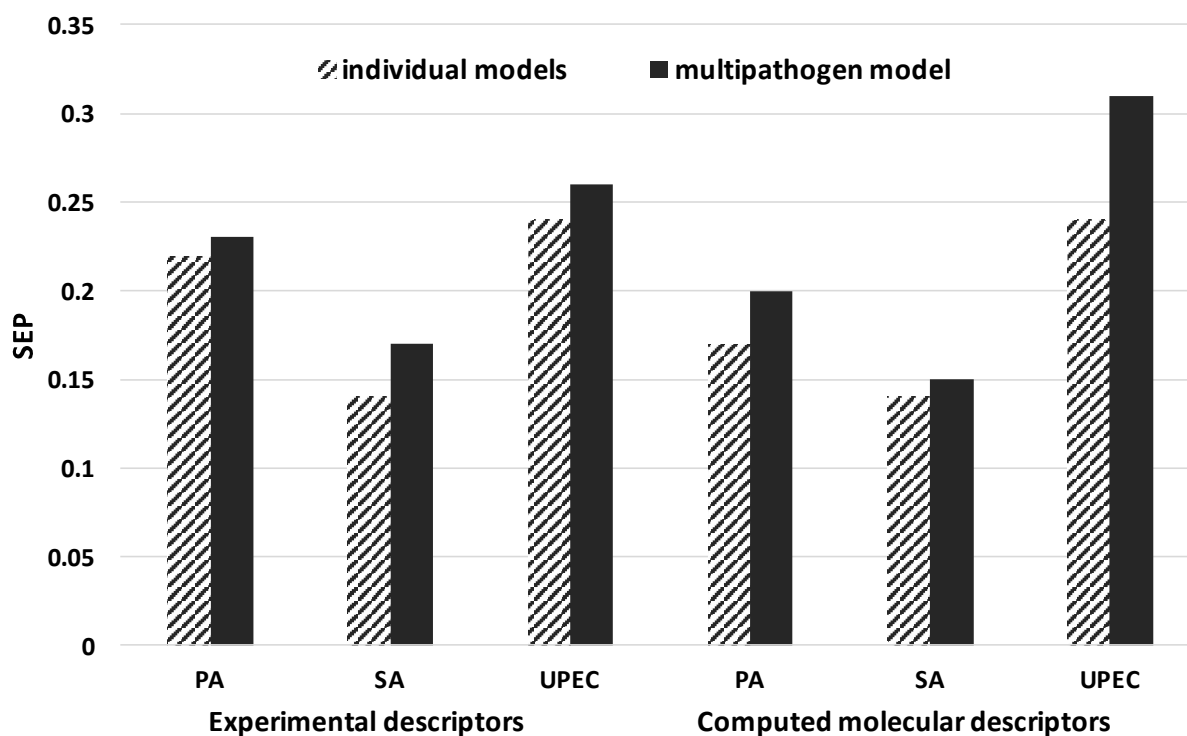

The attachment of the three pathogens to the polymer library are reasonably well correlated with each other, with  $r^2$  values greater than 0.5 for all species, as Table 3 shows. UPEC attachment shows good correlation with PA and SA, while PA and SA attachment are correlated to a slightly lesser extent. The significance of the pathogen indicator variables (1 when pathogen present and 0 when absent) to the attachment models was interesting. Only the UPEC indicator variable was statistically significant in the models, and the weights of the PA and SA indicator variables were similar and much smaller. Given the caveat that we are only examining single strains of each pathogen, we might imply that PA and SA may have more similar structure-property relationships and levels of attachment compared to UPEC.

**Table 3.** Correlation matrix ( $r^2$ ) for the attachment of the three pathogens to the polymer library.

|    | PA   | SA   | UPEC |
|----|------|------|------|
| PA | 1.00 | 0.52 | 0.66 |
| SA | 0.52 | 1.00 | 0.72 |

$$\text{UPEC} \quad | \quad 0.66 \quad 0.72 \quad 1.00$$

The differences between the single pathogen and multi-pathogen models for the two types of molecular descriptors are summarized in Tables 1 and 2. It is clear that there are not large differences in the predictive power of the single pathogen models compared to the multi-pathogen model for each family of descriptors. This is illustrated graphically in Figure 6, which summarizes the SEP values for pathogen attachment generated by pathogen-specific models or the by the multi-pathogen model. Clearly, the test set SEP values for predicted attachment from single pathogen models, are similar to those from the multi-pathogen models. This suggests strongly that multi-pathogen models are effective, and have quantitative predictive power that is similar to the individual pathogen models. Consequently, it should be feasible to generate models that can make accurate quantitative predictions of pathogen attachment to materials for more than three pathogens. The fact that such models can be derived relatively simply by use of indicator variables as descriptors shows that the structure-activity (attachment) relationships between the pathogens may be described well by a nonlinear additive function such as a log-linear relationship. There is also a degree of inductive transfer of knowledge (a type of ‘read across’) where internal models predicting the adhesion of each pathogen learn from each other.<sup>45</sup> It has been proposed relatively recently that multi-task machine learning models have improved generalization performance because they use information from related tasks as an inductive bias.<sup>46</sup> The efficacy of the multi-pathogen model may also be aided by the moderate correlations between the attachment of the three pathogens to the polymer library. Bacterial pathogens whose attachment to polymers are not as strongly correlated with each other may not be predicted as reliably by future multi-pathogen models.

**Figure 6.** Standard errors of prediction values for test set for single pathogen versus multipathogen models generated using molecular descriptors or experimental surface analytical ToF-SIMS descriptors.

#### *Models using computed versus experimental descriptors*

The results summarized in Tables 1 and 2 suggest that nonlinear models derived from computed and experimental descriptors have similar abilities to predict attachment of pathogens to polymers in the test set (SEP values of 0.19 and 0.21 logF). However, the linear model of pathogen attachment based on computed molecular descriptors had significantly better predictive power than that based on experimental ToF-SIMS and WCA descriptors (0.28 versus 0.33 logF). Consequently, it may be argued that it is not essential to obtain ToF-SIMS data for model generation, unless these types of experimental descriptors provide additional insight into the role

of surface chemistry on pathogen attachment compared with computed molecular descriptors. Table 4 summarizes the statistics of the two multi-pathogen models. Figure 7 compares the performance of the two descriptor types in predicting the attachment of the test set.

**Table 4.** Statistics of multi-pathogen attachment models. See Supplementary Tables S1 and S3 for details of the descriptors used in the models.

| Descriptor set | $N_{\text{hidden}}$ | $N_{\text{eff}}$ | $N_{\text{des}}$ | Training |       | Test |       |
|----------------|---------------------|------------------|------------------|----------|-------|------|-------|
|                |                     |                  |                  | SEE      | $r^2$ | SEP  | $r^2$ |
| Computed       | 7                   | 488              | 41               | 0.16     | 0.86  | 0.19 | 0.81  |
| Experimental   | 5                   | 378              | 79               | 0.12     | 0.76  | 0.21 | 0.74  |

1  
2  
3 **Figure 7.** Test set SEP values for the four pathogen attachment models for the two types of  
4 descriptors. The experimental descriptors were dominated by ToF-SIMS ion intensities and the  
5 WCA did not play a significant role.  
6  
7  
8  
9

10 The model using experimental ToF-SIMS ion peaks uses a less complex neural network  
11 architecture but more descriptors than the model using computed molecular descriptors.  
12 However, the number of effective weights in the model, derived from the Bayesian  
13 regularization, are similar. It is clear that both methods for encoding the molecular characteristics  
14 of the polymers generated very good, robust, and predictive attachment models, and the model  
15 quality is similar. The SEP values for all models derived using computed molecular descriptors  
16 are equal to or lower than those derived using experimental descriptors, as Figure 7 shows. The  
17 performance of the UPEC model using ToF-SIMS ions peak and computed molecular descriptors  
18 are comparable despite the model derived from ToF-SIMS descriptor being sparser (10 relevant  
19 descriptors compared to 18).

33

34 The weights of the descriptors in the linear multi-pathogen models gives some insight into the  
35 role surface chemistry plays in attachment of the three pathogens. The unweighted contributions  
36 the computed descriptors made to the model are shown in Figure 3. Curiously, in this linear  
37 model, the contributions that the PA and SA indicator variables made to the model were very  
38 similar, suggesting similar structure-property relationships at the polymer surfaces, and similar  
39 levels of pathogen attachment, despite having fundamentally different cell surfaces and signal  
40 transduction machineries (gram-negative vs gram-positive). In spite of being easy to calculate  
41 and capable of generating robust model that make good predictions of the attachment of  
42 pathogens to polymers, the molecular descriptors are quite arcane and difficult to interpret in  
43 terms of surface chemistry. The majority of computed descriptors make negative contributions to  
44

1  
2  
3 the attachment model, meaning that when these molecular properties are larger, pathogen  
4 attachment reduces. The largest negative contribution was from the PVSAs6 descriptor and the  
5 most positive contribution was from the TIC1 descriptor. The PVSAs6 descriptor is one of a  
6 group of P-VSA-like descriptors that is defined as the amount of the molecular van der Waals  
7 surface area (VSA) having a property P in a certain (binned) range.<sup>47</sup> TIC1 is the first order  
8 neighbourhood total information content of the molecule, a measure of molecular (graph)  
9 complexity. It is related to Shannon entropy.<sup>48</sup>

10  
11  
12 The unweighted contributions the sparse experimental descriptors make to this model are  
13 summarized graphically in Figure 5. Significantly, WCA makes a negligible contribution to  
14 pathogen attachment in either individual or multi-pathogen models. Previously Hook et al had  
15 also found no correlation between contact angle and pathogen attachment.<sup>23</sup> Conventional  
16 wisdom teaches that reduced bacterial attachment often requires bound water in hydrophilic  
17 structures. As noted by Hook et al previously, these relatively hydrophobic materials clearly do  
18 not function by that mechanism. This is consistent with the poor predictive power provided by a  
19 surface wettability parameter across these diverse material libraries for eukaryotic and  
20 prokaryotic cells, discussed in detail elsewhere.<sup>43</sup>

21  
22  
23 In the multi-pathogen attachment models using the ToF-SIMS surface analysis data, the  
24 indicator variables for the pathogen identity were also significant, with the UPEC indicator  
25 variable making a much larger negative contribution to the model than the PA and SA indicator  
26 variables. This may be due to the significantly lower average attachment of UPEC to the polymer  
27 library. The  $C_4H^+$  ion peak made the largest negative contribution to the model, approximately 3  
28 times larger than the next most significant ion peaks (Figure 5). The dominance of hydrocarbons  
29 in the ion fragments associated with negative loadings is consistent with the view that monomers

2  
3 with pendent hydrocarbon groups bonded to the ester moiety are more resistant to bacterial  
4 attachment. The exceptions are the  $C_2H_3^+$ ,  $C_3H^+$ ,  $C_6H_{11}^+$  and  $C_6H_6O^+$  ions that made positive  
5 contributions to the model. The  $C_2H_3^+$  fragment ion is present in the spectra of all polymers and  
6 is likely to have contributions from both the backbone and the polymer pendant groups. The  
7  $C_3H^+$  peak is present at elevated intensities in the mass spectra of monomers 7, 14 and is  
8 consequently assigned to a fragment of an aromatic ring.  $C_6H_{11}^+$  could be an aliphatic chain or a  
9 cyclohexane ring fragment (e.g. from monomer 5) but it makes negligible contribution to the  
10 multi-pathogen linear model in any case. The  $C_6H_6O^+$  ion fragment comes mostly from the  
11 phenol fragment present in monomer 7. These contributions towards the logF model imply that  
12 small aliphatic groups (all hydrophobic) on the meth/acrylate polymer were correlated with low  
13 bacterial attachment, as was previously reported by Hook et al. and Epa et al.<sup>23-24</sup> The more  
14 hydrophilic phenolic fragment  $C_6H_6O^+$  appears to enhance attachment of pathogens in the multi-  
15 pathogen model, again consistent with these previous studies. It was conjectured that the  
16 functional groups in the polymer facilitated hydrogen bonding with peptidoglycans, teichoic  
17 acids, proteins, lipopolysaccharides, lipoteichoic acids or exopolysaccharides present on the  
18 bacterial cell surface or that are component of biofilms.

There is relatively little difference between the test set standard errors of prediction (Figure 6)  
for models using computed or experimental descriptors (ToF-SIMS ion peak dominated). Models  
derived from experimental descriptors have larger prediction errors for the PA attachment but  
smaller errors for UPEC models (this may also be an artefact of the small training set size of this  
data set). Clearly the computed descriptors avoid the need for further experiments, but the  
experimental descriptors may be easier to interpret in terms of how the surface chemistry of the  
polymers influence pathogen attachment. Generally, for quantitative structure – property

1  
2  
3 relationship (QSPR) methods, use of computed molecular descriptors is desired as it allows  
4  
5 properties of new molecules to be predicted prior to synthesis. The use of experimentally-derived  
6  
7 data may be useful in cases where the characterization experiments have been carried out for  
8  
9 another purpose, or where other synthesis or processing properties have a significant effect on  
10  
11 their performance.  
12  
13

14  
15 As mentioned previously previous work on bacterial attachment modelling has been reported  
16  
17 Epa et al.<sup>24</sup>, Hook et al.<sup>23</sup> and Sanni et al.<sup>25</sup>. The simplest modelling approach was by Sanni et al.,  
18  
19 where the authors generated a linear attachment model using a composite descriptor derived  
20  
21 from the log of the octanol-water partition coefficient (logP) and number of rotatable bonds in  
22  
23 the monomer. The model was derived from only (meth)acrylate materials containing  
24  
25 hydrocarbon pendant groups and it failed to predict attachment for other chemistries that  
26  
27 promoted greater biofilm formation. The predictions inside this restricted chemical space domain  
28  
29 of applicability had an  $r^2$  of 0.67, good for such a simple linear model.  
30  
31

32  
33 Hook et al. employed a partial least squared (PLS) linear method using ions obtained from  
34  
35 ToF-SIMS experiments to find relationship between surface chemistry and bacterial attachment.  
36  
37 The authors were able to make relatively good models for PA and SA with  $r^2$  values of 0.68 and  
38  
39 0.76 respectively, while PLS failed to find a statistically valid predictive model for UPEC ( $r^2$   
40  
41  $<0.3$ ). In this paper, we were able to make substantially improved quantitative models predicting  
42  
43 the polymer attachment of all three pathogens (see Table 3). This shows that sparse selection of  
44  
45 features, combined with an optimal non-linear modelling method BRANN, can create  
46  
47 significantly improved predictive models compared to those generated by PLS or other linear  
48  
49 methods with the same or similar sets of descriptors.

1  
2  
3 Epa et al. sparse selection of computed, interpretable molecular descriptors generated bacterial  
4 attachment models consistent with those of the current study presented in Table 2. It is  
5 interesting to note that, despite different sets of descriptors being used, models of similar quality  
6 were obtained.

### 12 *Model predictions of pathogen attachment to a new polymer array*

13  
14 Prediction of the attachment properties of test sets partitioned from a large data set and never  
15 used to generate the model is a pragmatic way of measuring the predictivity power of  
16 computational models. However, the ultimate test is to predict the attachment properties of new  
17 polymers. The models derived for bacterial attachment from computed molecular descriptors  
18 were used to estimate bacterial attachment for two new libraries, one containing polymers made  
19 from 12 monomers (Supplementary Table S6), and the other containing 368 polymers derived  
20 from 21 monomers (Supplementary Table S7). Attachment data were obtained for PA and  
21 UPEC. As explained in the Methods section, these polymer attachment experiments used a  
22 different fluorescent protein, mCherry instead of GFP to generate the data used to validate model  
23 predictions. Differences between the different fluorophores meant that quantitative comparisons  
24 between the predicted and measured pathogen attachment to these new monomers could not be  
25 made, and classification methods were employed. Predictions were made for low, medium, or  
26 high pathogen of polymers in the two new libraries based on the distribution of predicted logF  
27 values. Predictions of the multi-pathogen and single pathogen attachment (log GFP fluorescence)  
28 models were also normalized and assigned to the low, medium and high attachment classes.  
29 Prediction accuracy was assessed by use of truth tables, and the percentage of class membership  
30 correctly predicted.  
31

48  
49  
50  
51

52  
53 As the truth tables for classification by models in Supplementary Figure S7 show, the  
54 individual pathogen attachment models had similar accuracies to the multi-pathogen models at  
55  
56  
57  
58  
59  
60

1  
2  
3 predicting the class membership of the new materials in both new polymer arrays. The class  
4  
5 membership for attachment of PA to the larger polymer library was predicted with accuracies of  
6  
7 60% and 71% for the multi-pathogen and specific PA models respectively. The class  
8  
9 membership prediction accuracies were slightly lower for the smaller validation polymer library.  
10  
11 In this case PA attachment was predicted with 55% and 40% accuracies for the multi-pathogen  
12  
13 model and specific PA model respectively. Given that classes would be assigned correctly 33%  
14  
15 of the time by chance, the specific PA model attachment to the smaller polymer library  
16  
17 predictions are not statistically significant but those of the multi-pathogen model are. Adhesion  
18  
19 of UPEC to polymers is generally lower and the experimental error larger, however, both models  
20  
21 predicted the class membership with reasonable accuracies (39% and 46% for multi-pathogen  
22  
23 and single pathogen models respectively). Although this study did not allow us to assess the  
24  
25 predicted pathogen attachment to new polymer libraries quantitatively, it does strongly suggest  
26  
27 that the models have useful predictive capabilities that will be helpful in selecting improved  
28  
29 materials with the ability to resist the attachment and biofilm formation for multiple pathogens.  
30  
31  
32  
33  
34

## 35 **Conclusions**

36  
37  
38 We have shown that it is possible to predict the individual attachment of three important  
39  
40 pathogens to a library of copolymers using a *single* model that employs a specific set of  
41  
42 descriptors. This model can predict the attachment of each pathogen to the polymers with  
43  
44 accuracies similar to those of models specifically trained to predict a single pathogen. This offers  
45  
46 the possibility of developing a generalized description of the response of multiple bacterial  
47  
48 strains to materials. This could ultimately become a framework with which new materials with  
49  
50 broad pathogen resistance can be designed and optimized, rather than relying on ‘one-pathogen-  
51  
52 at-a-time’ modelling methods now widely used. Such new materials promise reduced materials-  
53  
54  
55

57  
58  
59  
60

1  
2  
3 associated infections in the clinic and more broadly in other non-clinical applications where  
4 formation of biofilms is problematic. We anticipate the multi-pathogen modelling approach may  
5 be extendable to more than three pathogens and to experiments where several bacterial species  
6 (or strains) are coexisting. This will open the way for a comprehensive predictive capability that  
7 could be used to assess the suitability of novel materials for highly effective implantable  
8 materials.

## TOC

Bacterial infections are common in implanted medical devices used to manage chronic health conditions. Device infection and pathogen tolerance to antibiotics can be reduced by polymers that resist the formation of bacterial biofilms. We show that a single machine learning model can predict attachment of multiple pathogens to polymers for the first time, accelerating development of new, low pathogen attachment materials.
