24 **ABSTRACT**

25 Behavioural mimicry is a potential mechanism explaining why adolescents appear to be
26 influenced by their parents' eating behaviour. In the current study we examined whether there
27 is evidence that adolescent females mimic their parents when eating. Videos of thirty-eight
28 parent and female adolescent dyads eating a lunchtime meal together were examined. We
29 tested whether a parent placing a food item into their mouth was associated with an increased
30 likelihood that their adolescent child would place any food item (non-specific mimicry) or the
31 same item (specific mimicry) in their mouth at three different time frames, namely during the
32 same second or within the next fifteen seconds (+15), five seconds (+5) or two second (+2)
33 period. Parents and adolescents' overall food intake was positively correlated, whereby a
34 parent eating a larger amount of food was associated with the adolescent eating a larger meal.
35 Across all of the three time frames adolescents were more likely to place a food item in their
36 mouth if their parent had recently placed that same food item in their mouth (specific food
37 item mimicry), however there was no evidence of non-specific mimicry. This observational
38 study suggests that when eating in a social context there is evidence that adolescent females
39 may mimic their parental eating behaviour, selecting and eating more of a food item if their
40 parent has just started to eat that food.

41

42 Social context has been shown to have a strong influence on eating behaviour (Herman, Roth
43 & Polivy., 2003; Goldman et al., 1991). Social modelling research has shown that the eating
44 behaviour of adults and children can be influenced by the amount of food other diners are
45 eating; eating more when others are eating more and less when they are eating less
46 (Bevelander et al., 2012; Hermans et al., 2009). A variety of potential explanations of these
47 effects have been suggested. For example, modelling may occur because the behaviour of
48 one's peers sets a norm of what constitutes a socially appropriate amount to eat (Herman et
49 al., 2003; Vartanian et al., 2013) or because it acts as an informational cue to guide behaviour
50 (Robinson et al., 2013).

51

52 Parents are thought to be one of the most important social influences on child and adolescent
53 eating behaviour (Salvy et al., 2011), influencing health beliefs, behaviours and dietary intake
54 (Oliveria et al., 1992; Lau et al., 1990). Moreover, parental and child food consumption tend
55 to be correlated in terms of the type and amounts of food that both eat (McGowan et al.,
56 2012; Wroten et al., 2012; Sweetman et al., 2011). Likewise, research has shown that
57 children are more likely to try a food if they observe their parent eating that same food
58 (Harper et al., 1975). More recent research has also shown in an experimental setting that the
59 presence of a parent shapes the amount and types of food adolescents eat (Salvy et al., 2011).
60 However, the mechanisms underlying the processes by which adolescents adapt their eating
61 to match parental behaviour when eating has received less attention.

62

63 One possibility is that adolescents mimic or synchronise to their parents' eating behaviour
64 when dining together. Behavioural mimicry refers to the process whereby a person imitates
65 the behaviour of another person without conscious awareness and is thought to occur due to a
66 tight neural link between perception and action (Chartrand & Bargh., 1999; Chartrand et al.,

67 2009), such that observing another person's movements may trigger one's own motor system
68 to perform that same movement (Lakin & Chartrand., 2003; Iacoboni., 2009), e.g. taking a
69 bite of food. Mimicry has been suggested to occur for a number of behaviours (Larsen et al,
70 2009; Neumann & Strack., 2000; Bernieri., 1988) and more recently the role of behavioural
71 mimicry in social eating contexts has been examined. Hermans et al. (2012) found that when
72 two female adults ate the same meal together, participants were more likely to pick up and eat
73 the food if their eating partner had done so in the proceeding five seconds. Similarly,
74 Bevelander et al. (2013) found that when a young child (aged 6-11) picked up and ate a
75 chocolate covered peanut, this was associated with an increased likelihood that their eating
76 partner would subsequently pick up and eat that food. Thus, previous studies have only
77 investigated behavioural mimicry in child only or adult only groupings (Hermans et al., 2012,
78 Bevelander et al., 2013) and as research supports that adolescents' eating behaviour may be
79 affected by the eating behaviour of a present parent (Salvy et al., 2011), it will be important
80 to understand whether mimicry of eating behaviour may occur between a parent and an
81 adolescent. It may be the case that mimicry of parental eating is a mechanism explaining
82 parental influence on adolescent eating behaviour.

83

84 In studies to date examining behavioural mimicry during social eating, participants have only
85 been provided with a single food item to eat (Hermans et al., 2012; Bevelander et al., 2013).
86 From these studies it is therefore not possible to infer whether participants were mimicking
87 eating of a specific food type (if you take food x, I then take food x) or whether participants
88 were simply synchronising the rate of their food intake in a more general/non-specific
89 manner. For example, it may be that watching another person pick up a food item triggers an
90 automatic reaction to reach for any food item (non-specific food item mimicry) or only the
91 same food item (specific food item mimicry). Differentiating between these two possibilities

92 is of importance because it may signal mechanisms that underlie mimicry. If automatic
93 synchrony of gestures is of importance (Hermans et al., 2012; Iacoboni et al., 1999) then we
94 may expect to see evidence for non-specific mimicry, because mimicry of the action of eating
95 is key. Conversely, if mimicry occurs because an eating partner sets a norm about which
96 foods are and are not appropriate to eat (Vartanian et al., 2013; Herman et al., 2003), then
97 only mimicry of congruent food items may be observed. These questions are also of
98 importance because in naturalistic social eating contexts such as family meal times, a variety
99 of food items are likely to be available.

100

101 In the present study we aimed to examine whether there is evidence that adolescents mimic
102 the eating behaviour of their parents when eating together. In order to assess mimicry, videos
103 of parent-adolescent dyads eating a multi-item lunchtime meal were examined. We examined
104 whether there was evidence of both ‘non-specific food item mimicry’ and ‘specific food item
105 mimicry’. Based on previous studies of eating mimicry (Bevelander et al., 2013; Hermans et
106 al., 2012), it was hypothesised that a parent placing a food item in their mouth would be
107 associated with an increased likelihood that their adolescent child would also place a food
108 item in their mouth. However, we reasoned that if evidence of mimicry was observed, it may
109 only be food item specific, as parental behaviour during a meal may primarily signal which
110 foods are appropriate to eat and when.

111

112

113 **METHOD**

114 *Background*

115 The videos analyzed were of adolescents and parents eating a multi-item lunchtime meal
116 together, which were recorded as part of a test day for a larger study examining brain

117 activations and responsiveness to food cues. In the larger study, participants arrived at the
118 laboratory on the morning of their test day where they underwent an MRI scanning session,
119 which was followed by a multi-item lunch. Participants were aware that their lunch time meal
120 would be video recorded. However, participants were not explicitly told that their food intake
121 would be measured or that mimicry would be later examined. Three groups of participants
122 were recruited as part of the larger study; adolescents with type 2 diabetes, overweight and
123 obese adolescents (without type 2 diabetes) and healthy weight adolescents (without type 2
124 diabetes). See supplemental material for more detailed information about the selection criteria
125 for the larger study.

126

127 *Participants*

128 From the original data collected we were unable to use ten videos due to equipment failure or
129 error and one video was excluded because the participant did not eat anything. In addition,
130 we opted to focus on female adolescents only, due to the consistency of which social
131 influence effects have been replicated amongst females (Hermans et al., 2012; Pliner and
132 Mann., 2004; Roth et al., 2001) and there only being a small number of videos of adolescent
133 males available. Therefore, nine videos of adolescent males were not coded or analyzed.
134 Thus, the total sample for the present research consisted of 38 dyads containing female
135 adolescents eating with a parent. See Table 1 for sample ethnicity and socio-economic status.
136 There were 33 female parents and 5 male parents. The adolescents were aged 12.0 – 18.8
137 years, with a mean age of 15.4 years, SD = 1.9. Adolescent weight categories were classified
138 according to the defined International Obesity Task Force age specific cut offs (Cole et al,
139 2000, Cole et al, 2007). Eleven of the adolescents were classed as being in the healthy weight
140 range (BMI 18.5-24.9), fourteen were classed as overweight and obese (BMI \geq 25) and
141 thirteen had type 2 diabetes (BMI = 17.3-57.1). For the total sample mean adolescent BMI =

142 30.6, SD = 9.7. Mean parental BMI = 30.1, SD = 5.8. See Table 2 for adolescent and
143 parental BMI information for the healthy weight, overweight and obese, and diabetic groups
144 separately.

145

146 For our planned analyses we did not have any hypotheses relating to whether the weight or
147 diabetes status of adolescent participants would moderate or influence any tendency to mimic
148 parental eating, because social influence on food intake has been shown to be a relatively
149 consistent effect and observed to a similar degree in both healthy weight and overweight
150 individuals (Conger et al., 1980, Herman et al., 2003, Robinson et al., 2014). We did however
151 check if this was the case by conducting our planned analyses (see later section) and included
152 adolescent group (healthy weight, overweight and obese, diabetic) as an additional factor.

153 There was no evidence that adolescent group significantly moderated any mimicry effects (p
154 > 0.05). Thus, as the number of adolescents in each group was relatively small and we did not
155 have strong a-priori hypotheses, the results we report throughout are for all adolescent
156 participants combined.

157

158 *Lunch time meal*

159 All sessions took place in an eating laboratory at the University of Birmingham. The room
160 was furnished with a table and two chairs. Adolescents and parents were served a
161 standardized multi-item meal each on separate trays. Each lunch item was on a separate plate
162 and the meal consisted of a cheese sandwich (369 kcals), an individual Chicago Town cheese
163 pizza (453 kcal), small bowl of cherry tomatoes (18kcal), an Activia strawberry yoghurt (123
164 kcal), an apple (45kcal), a Satsuma (18kcal), 25g Walkers ready salted crisps (131 kcal) and
165 two Maryland double chocolate cookies (112kcal). A jug of water and 2 glasses was also
166 provided. They were asked not to share food from each other's trays and told that they were

167 not expected to eat all the food, but to eat until they were full. The lunchtime meals were
168 recorded using video cameras and participants were made aware of this prior to participating
169 in the study.

170

171

172 **ANALYSIS**

173 *Strategy of analysis for overall food consumption*

174 Our first aim was to test whether there was evidence that adolescents' overall consumption
175 may have been influenced by their parents' consumption. We did this by correlating the total
176 amount of food adolescents ate (in kcals) with the amount of food their parent ate (kcals)
177 using a Spearman's correlation.

178

179 *Coding of video data*

180 The first step in order to investigate whether there was evidence that the adolescents may
181 have mimicked the eating of their parents was to code the video data by recording every time
182 an adult or adolescent placed a food item into their mouth, the name of that food item (e.g.
183 pizza) and the time that the food entered the mouth. All occurrences of eating were recorded
184 by the first author. A random sample constituting 10% of these codings were independently
185 checked by one of the other authors and there were no disagreements. The first author then
186 coded each time an adolescent placed food into their mouth during the sensitive and non-
187 sensitive time periods of the meal (see next section '*Defining sensitive and non-sensitive*
188 *periods*'). All of this coding was then cross-checked by an independent research assistant
189 blind to the study hypotheses. Only a small number of discrepancies were noted (7 instances
190 of mimicry were coded incorrectly, which constituted less than 1% of total coding) and they
191 were resolved after discussion between the research assistant and lead author.

192

193 *Defining sensitive and non-sensitive periods*

194 Previous studies have examined if participants are more likely to eat a food item in the 5 or
195 15 seconds after a dining partner has placed food in their mouth (known as a ‘sensitive
196 period’), in comparison to the other periods of the meal when a partner had not recently
197 placed food into their mouth (known as a ‘non-sensitive period’) (Hermans et al., 2012;
198 Bevelander et al., 2013; Larsen et al., 2010). In the present study we examined three sensitive
199 time period cut off points (+2, +5, +15 seconds), because we reasoned that mimicry may also
200 occur in a shorter time frame (i.e. within + 2 seconds of a person eating) than previous studies
201 have tested, as mimicry has been suggested to be automatic (Iacoboni et al., 1999). The three
202 timeframe cut off points (+2, +5, +15) were treated as *separate* timeframes. Each meal was
203 split into sensitive (the times during the meal in which a parent had recently placed food into
204 their mouth) and non-sensitive time periods (all other times during the meal; i.e. the times
205 during the meal in which a parent had not recently placed food in their mouth) for each of the
206 three *separate* time frames (+2, +5, +15). This approach would allow us to test whether the
207 rate at which adolescents placed food into their mouth differed between *sensitive* vs. *non-*
208 *sensitive* periods, for the three time frames individually. See ¹ for a detailed example. We
209 presumed that if adolescents ate at a quicker rate during sensitive vs. non-sensitive periods,
210 this would constitute evidence of mimicry. We calculated the rate of placing food into the
211 mouth (defined as a consumption ratio, see next section) as opposed to just the number of
212 times food was placed in the mouth, in order to account for there being differences in total
213 sensitive vs. non-sensitive time during each meal.

214

215 *Strategy of analysis for mimicry*

216 As noted, we coded how frequently adolescents placed food items into their mouth during the
217 sensitive periods (times when the parent **had** recently placed food in their mouth) and during
218 the non-sensitive periods (times when the parent **had not** recently placed food in their mouth)
219 of the lunchtime meal, for the three time frames separately. We then quantified this formally
220 by computing ‘consumption ratios’; the number of times a food item was placed into an
221 adolescents’ mouth per second². Following this we compared the consumption ratio observed
222 for the sensitive periods vs. non-sensitive periods of the meal using a Wilcoxon signed ranks
223 test³ for the three different time frames individually (+2, +5, +15). We adjusted the analyses
224 using a Bonferroni correction to account for multiple comparisons. This allowed us to
225 compare the consumption ratios (the number of times a food item was placed into an
226 adolescents’ mouth per second) for the periods of the meal in which a parent had recently
227 placed into their mouth vs. periods of the meal in which the parent had not recently placed
228 food into their mouth. Importantly, we computed these consumption ratios for both *non-*
229 *specific* food item mimicry and *specific food* item mimicry.

230

231 *Non-specific food item mimicry*

232 In order to compute consumption ratios for **non-specific** food item mimicry we used the
233 aforementioned analysis strategy and examined the rate at which adolescents placed **any** food
234 item into their mouth during the sensitive periods vs. the rate at which adolescents placed **any**
235 food into their mouth during the non-sensitive periods. This analysis allowed us to examine
236 whether adolescents more frequently placed **any** food item in their mouth in periods when
237 their parent had recently placed **any** food item in their mouth, as opposed to periods of the
238 meal when a parent had not recently placed **any** food in their mouth.

239

240 *Specific food item mimicry*

241 In order to compute consumption ratios for **specific** food item mimicry here we instead
242 examined the rate at which adolescents placed the **same** food item into their mouth which
243 their parent had placed in their mouth in the proceeding 2, 5, or 15 seconds (sensitive period)
244 vs. times when the parent **had not** placed a food item into their mouth in the proceeding 2, 5,
245 or 15 seconds (non-sensitive periods). This analysis allowed us to examine whether
246 adolescents more frequently placed a food item in their mouth in the periods of the meal in
247 which their parent had recently placed the **same** food item in their mouth, as opposed to all
248 other time periods of the meal.

249

250 Thus, we were able to examine whether there was evidence of *specific* food item and *non-*
251 *specific* food item mimicry using +2, +5 and +15 time frames individually.

252

253 **RESULTS**

254 *Total food intake*

255 Parents ate a mean of 816.1 (± 204.8) calories during the lunchtime meal and adolescents ate a
256 mean of 697.6 (± 238.3) calories during the meal. A Spearman's correlation showed that the
257 amount eaten by the parents and children was significantly correlated [$r(38) = .49, p < .001$],
258 whereby a parent eating a larger number of calories was associated with their adolescent child
259 also eating a larger number of calories.

260

261 *Meal length and frequency of food being placed into the mouth*

262 Mean meal length was 18 minutes and 13 seconds (SD = 6.37). The mean number of times
263 that parents placed any food item into their mouth was 59.50 (SD = 19.07). The mean number
264 of times that adolescents placed any food item into their mouth was 77.84 (SD = 24.19). On
265 average, parents placed food into their mouth every 19.88 seconds (SD = 8.98), which

266 constitutes a mean consumption ratio = 0.06 bites per second during the meal, while,
267 adolescents placed food into their mouth every 14.53 seconds (SD = 4.93) on average, which
268 constitutes a mean consumption ratio = 0.08 bites per second during the meal.

269

270 *Non-specific mimicry*

271 There was little evidence of non-specific food item mimicry during the meal. The
272 consumption ratios for each of the three sensitive time periods were not significantly higher
273 than the consumption ratios observed during the equivalent non-sensitive periods; +2 ($z = -$
274 $.17, p = .26, r = -.03$) +5 ($z = -1.47, p = .42, r = -.24$), and +15 ($z = -2.27, p = .06, r = -.37$). See Table
275 3 for consumption ratio values. This indicates that the rate at which adolescents placed any
276 food into their mouth (the consumption ratios) were similar in the periods of the meal in
277 which their parent had recently placed any food into their mouth (sensitive periods) and all
278 other periods of the meal in which their parent had not recently placed any food into their
279 mouth (non-sensitive periods), regardless of whether ‘sensitive’ was defined as being within
280 +2, +5 or +15 seconds after a parent had placed food into their mouth. Thus, it was not the
281 case that adolescents were significantly more likely to place any food item into their mouth if
282 their parent had recently placed a food item into their mouth.

283

284 *Specific mimicry*

285 For specific food items, there was evidence of mimicry for the +2 ($z = -3.42, p < .001, r = -$
286 $.55$), +5 ($z = -3.90, p < .001, r = -.63$) and +15 ($z = -3.73, p < .001, r = -.60$) second timeframes,
287 as consumption ratios during these sensitive time periods were higher than the consumption
288 ratios observed during the equivalent non-sensitive periods. See Table 3 for consumption
289 ratio values. This indicates that the rate at which adolescents placed a food into their mouth
290 was greater in the periods of the meal in which their parent had recently eaten that same food

291 item (sensitive periods) compared to the other remaining periods of the meal in which their
292 parent had not recently eaten that same food item (non-sensitive periods), regardless of
293 whether ‘sensitive’ was defined as being within +2, +5 or +15 seconds after a parent had
294 placed food into their mouth. Thus, there was evidence that adolescents were significantly
295 more likely to place a food item in their mouth if their parent had recently placed that same
296 food item into their mouth.

297

298

299 **DISCUSSION**

300 The present study examined whether there is evidence that female adolescents may mimic
301 their parents when eating together during a lunchtime meal. In line with previous work (Story
302 et al., 2002), there was evidence of a positive correlation between parent and adolescent food
303 consumption; adolescents consumed more calories during their lunch when their parent
304 consumed more calories. We also examined if behavioural mimicry may underlie the
305 influence that parents can have on their adolescents’ eating behaviour. Results indicated that
306 a parent placing a food item into their mouth was associated with an increased likelihood that
307 their adolescent child subsequently picked up and ate the *same* food item during the
308 following two, five and fifteen second periods. However, we did not find evidence that a
309 parent placing a food item into their mouth was associated with an increased likelihood of
310 their child placing *any* food item into their mouth in these time periods. Thus, adolescents
311 appeared to mimic eating of specific food items only.

312

313 As in previous eating behaviour studies in adults and children (Hermans et al., 2012;
314 Bevelander et al., 2013) this observational data appears to support behavioural mimicry of
315 eating. However, the current study expands on these previous studies as we found evidence of

316 behavioural mimicry in a different dyad than has previously been examined (adolescents and
317 parents) and we were able to test whether adolescents mimicked the *specific* type of foods
318 their parents were eating, or whether this process of mimicry was not food item specific; i.e.
319 whether the parent placing a food into their mouth would simply increase the likelihood that
320 the adolescent would place any food in their mouth. The findings of the present study suggest
321 that adolescents were not simply synchronising their gestures or eating speed to match their
322 parents (due to a lack of evidence for non-specific mimicry), as has been previously
323 suggested as a potential explanation for social influence on eating (Hermans et al., 2012).
324 Instead adolescents may have been using their parents as a reference point about which food
325 items to eat and when, which could be interpreted through either a normative or informational
326 account of social influence on eating (Robinson et al., 2013; Herman et al., 2003), although
327 further studies will need to address this proposition more directly. The main novel finding of
328 the present work was that we found evidence of specific food item mimicry during a shorter
329 time frame (during the same or subsequent two seconds after a parent had placed food into
330 their mouth), and within a different relationship than has been previously tested (Hermans et
331 al., 2012; Bevelander, 2013), which suggests that there may be evidence for mimicry of
332 eating behaviour in a shorter time frame than has been previously assumed.

333

334 One possibility is that we did not find evidence for non-specific mimicry (i.e. a parent placing
335 food into their mouth was not associated with an increased likelihood that the adolescent
336 subsequently placed *any* food into their mouth) because the rate of adolescent eating was
337 relatively high during the meal. It could be argued that a high eating pace across all periods of
338 the meal would make it difficult to observe differences between periods of the meal in which
339 a parent had vs. had not recently eaten, possibly due to a form of ceiling effect. Further
340 research examining food-item specific vs. non-food item specific mimicry in other meal

341 settings which promote a slower pace of eating would now be valuable. It is also possible that
342 the influence parents appeared to have on adolescent eating may be in part explained by a
343 form of visual attentional bias (Laibson, 2001, Wardle, 2007, Hardman et al, 2014), whereby
344 adolescents visually followed parental gaze or hand movement to food choices, and parents
345 visually attending to a specific food increased the likelihood that the adolescent then followed
346 that cue and ate the same food.

347

348 A strength of the present study was that we examined parent-adolescent child dyads eating in
349 a semi-naturalistic environment, rather than examining behavioural mimicry when a member
350 of the dyad had been instructed on how much to eat (i.e. the confederate) (Hermans et al.,
351 2012; Bevelander et al., 2013). Moreover, we examined mimicry during a multi-item lunch
352 time meal and this allowed us to examine the extent to which adolescents mimicked specific
353 food choices. It is not clear whether this finding of specific mimicry is unique to this dyad or
354 whether it may occur in other relationships, therefore, further research is now needed. Due to
355 the cross-sectional nature of the present study one possibility we cannot rule out is that some
356 of the specific mimicry we observed may have been explained by the adolescents and parents
357 already sharing similar meal/food item order preferences, thus, further work could build on
358 the findings reported here by examining the effect of experimentally manipulating a parent's
359 behaviour during a meal on the extent to which their adolescent child mimics this behaviour.
360 One limitation that could also be addressed in further work is to investigate evidence of
361 mimicry between adolescent males and their parents. Here our sample was female. However,
362 recently Bevelander et al (2013) found that both male and female children (6-11 years old)
363 were more likely to eat after witnessing a peer reaching for snack food than without such a
364 cue. Therefore, it is possible that adolescent males may model the eating behaviour of their
365 parents, and that mimicry may underlie this modelling. Finally, we did not examine whether

366 state (e.g. hunger) or trait (e.g. the quality of the relationship between the parent and
367 adolescent) factors may have moderated the likelihood of mimicry, so further work designed
368 to specifically explore the factors which may make mimicry more or less likely would now
369 be valuable.

370

371 *Conclusions*

372 This observational study suggests that when eating in a social context there is evidence that
373 adolescent females may mimic their parental eating behaviour, selecting and eating more of a
374 food item if their parent has just started to eat that food.

375

376 **Notes**

377 ¹ Taking the +2 time frame as an example, the ‘sensitive periods’ of the meal were all
378 seconds of the meal which occurred within the same or next 2 seconds after a parent had
379 placed food into their mouth. The ‘non-sensitive’ periods of the meal were all other seconds
380 during the meal. Likewise, for the +5 time frame, the ‘sensitive periods’ of the meal were all
381 seconds of the meal which occurred within the same or next 5 seconds after a parent had
382 placed food into their mouth. The ‘non-sensitive’ periods of the meal were all other seconds
383 during the meal. Thus, for each participant the meal was split into ‘sensitive’ and ‘non
384 sensitive’ time using three different sensitive period cut-off points (+2, +5, +15 seconds).

385 ² Consumption ratios were calculated by counting the number of times that the adolescent
386 placed food into their mouth within a period and dividing this by the total amount of seconds
387 in that period.

388 ³ In the Wilcoxon signed ranks test the sensitive periods were deducted from the non-
389 sensitive periods. The negative ranks indicate the sensitive periods while the positive ranks
390 indicate the non-sensitive periods. No ties were observed in the analysis.

501

502

503

504 **Table 3.** Consumption ratios for food item specific and non-food item specific mimicry
 505 during sensitive and non-sensitive periods (n=38)

506

	Food item specific mimicry		Non-food item specific mimicry	
	Sensitive	Non-sensitive	Sensitive	Non-sensitive
	+2 seconds			
Mean (SD)	0.02 (0.02)	0.01 (0.03)	0.08 (0.03)	0.08 (0.04)
Median	0.02*	0.01	0.07	0.07
	+5 seconds			
Mean (SD)	0.02 (0.02)	0.01 (0.01)	0.08 (0.03)	0.08 (0.05)
Median	0.02*	0.01	0.07	0.07
	+15 seconds			
Mean (SD)	0.02 (0.02)	0.01 (0.01)	0.07 (0.03)	0.10 (0.11)
Median	0.02*	0.01	0.07	0.07

507

508 Consumption ratios indicate the number of times per second adolescents placed a food item
 509 into their mouth within sensitive and non-sensitive periods. A higher ratio indicates a greater
 510 rate of placing food items into the mouth.

511 *indicates a significant difference between the sensitive and non-sensitive consumption ratios
 512 at $p < 0.01$.
