11
12 **Abstract:** Modeling landscape evolution requires quantitative estimates of erosional processes. Dating
13 erosional landscape features such as escarpments is usually difficult because of the lack of datable deposits.
14 Some escarpments and valley margins are associated with the formation of mass-movement caves, sometimes
15 known as 'gull' or 'crevice' caves, which are typically restricted to within 0.5 km of the valley margin or scarp
16 edge. As in other caves, these mass-movement cavities may host speleothems. As gull-caves only develop
17 following valley incision, uranium-series dating of speleothems within them can provide a minimum age for
18 the timing of valley excavation and scarp formation. Here we present data from several gull-caves in the
19 Cotswold Hills, which form the eastern flank of the Severn valley in southern England. U-series ages from these
20 gull caves yield estimates for both the minimum age of the Cotswold escarpment and the maximum scarp
21 retreat rate. This is combined with data from geological modeling to propose a model for the evolution of the
22 Severn Valley and the Cotswold Hills. The data suggests that the location of the escarpment and regional
23 topography is determined not by valley widening and scarp retreat, but the in-situ generation of relief by
24 differential erosion.

25 Quantifying rates of landscape processes is an essential requirement for constructing, validating and
26 constraining increasingly sophisticated landscape evolution models (Pazzaglia, 2003; Tucker and
27 Hancock, 2010). With quantitative data, rates of landform development can be evaluated, enabling
28 the relative importance of geomorphological processes to be established and facilitating the
29 development of more realistic landscape evolution models. Moreover, quantification is extremely
30 important in predictive work, as it is required for estimating the impact of future global climate
31 change. Whilst some geomorphological processes can be easily quantified, such as the rate of valley
32 incision by dating river terrace sequences (Maddy, 1997; Maddy and Bridgland 2000; Maddy et al.,
33 2000; Maddy et al., 2001), dating cave levels in carbonate terrains (Farrant et al., 1995; Palmer,
34 2007), or by dating other alluvial materials such as tufa (Banks et al., 2012), deducing the timing and
35 rates of other processes such as valley widening and escarpment (or 'scarp') retreat is harder to
36 determine. However, both rates of valley incision and scarp retreat are required to understand how
37 valleys evolve. Do they develop by progressive incision and valley widening through fluvial channel
38 migration and concurrent hill slope retreat or is the gross relief generated 'in-situ' by the progressive
39 removal of the more erodible lithologies over multiple glacial-interglacial cycles? In the latter
40 scenario, valley width is influenced more by lithological heterogeneity and variable susceptibility to
41 periglacial weathering (Murton and Belshaw, 2011), dissolution and mass-movement rather than by
42 fluvial processes.

43 Some estimates of scarp retreat have been calculated from dating talus flatirons (also known as
44 tripartite slopes and triangular slope facets), for example Gutiérrez-Elorza and Sesé-Martínez (2001).
45 Fleming et al., (1999) used cosmogenic isotopes to date a basalt escarpment in South Africa. By
46 calculating the exposure age of the escarpment face, they were able to estimate the rate of cliff
47 back-wearing. Another method, proposed here, is to estimate the age of an escarpment by dating
48 mass-movement fissures that, under favorable conditions, develop along the escarpment edge.
49 These fissures, known as gulls, gull-caves (when large enough to enter), windy pits or crevice caves
50 (Halliday, 2004), open up when cambering and mass-movement enable the more competent cap-
51 rock to move valley-ward following valley incision. These tectonically widened fissures occur in a
52 wide variety of rock types, not just limestone, and are a global phenomenon. Like other caves, these
53 fissures may contain speleothem deposits which can be precisely dated using uranium series
54 methods (Lenart and Pánek, 2013). As the gull-caves can only develop after a scarp has formed, the
55 basal age of the oldest speleothems within them provide a *minimum* age for cave inception and
56 hence scarp formation. Moreover, as the gull-caves only form close to the scarp edge, they can be
57 used to determine a chronology of scarp retreat. Taken together with rates of valley incision
58 determined from fluvial terraces, the spatial and temporal pattern of valley development and scarp
59 formation can be resolved and models of regional landscape evolution erected.

60 **The study area**

61 In this paper, we use the lower Severn valley and the Cotswold Hills in southern England (Figure 1) to
62 test this methodology, and then construct a more realistic regional landscape evolution model based
63 on the data. The lower Severn valley between Worcester and Bristol forms a major feature in the
64 British landscape. Its origin and its relationship to the development of rivers such as the Thames
65 draining east to the North Sea has been the subject of debate (Maddy, 2002; Watts et al., 2000,
66 2005; Lane et al., 2008; Bridgland and Shreve, 2009). Quantifying the rate, timing and mechanisms of
67 valley widening and scarp retreat can help resolve this debate. This requires setting the evolution of
68 the region and the surrounding uplands into a chronological framework. Like many river systems,
69 the timing of valley incision is relatively well-constrained from river terraces; what is less well-known
70 is how the valley morphology developed during this time, particularly around the interfluvies away
71 from the main terrace thalweg.

72 The lower Severn valley is a wide, flat-bottomed vale up to 20 km wide and typically around 250 m
73 deep, draining south-west to the Severn Estuary. The western edge of the valley comprises the
74 Malvern Hills and the Forest of Dean. These uplands, underlain by Neoproterozoic and Palaeozoic
75 rocks mark the faulted western margin of the Worcester Basin. Much of the low-lying ground in the
76 centre of the valley, aside from some Palaeozoic rocks exposed north of Bristol, is underlain by
77 Triassic and Lower Jurassic (Lias Group) mudstones (Figure 1) that occupy the core of this basin. The
78 eastern side is marked by the prominent escarpment of the Cotswold Hills (or 'Cotswolds'), which
79 comprise a sequence of gently dipping interbedded limestones and mudstones (Figure 2) of Early to
80 Mid Jurassic (Pliensbachian to Bathonian) age (Barron et al., 2002, 2011). The escarpment extends
81 for about 100 km between Broadway Hill north-east of Cheltenham south to Bath, rising up to a
82 maximum of 320 m above sea-level (asl) on its up-dip edge. To the east of the scarp the hills are
83 characterized by a gently sloping, dissected plateau surface around 20 km wide, cut by numerous
84 deep valleys, especially around Bath and Stroud. Geological mapping clearly shows this topographic
85 surface is not a true stratigraphic dip-slope, and dips at a shallower angle than the bedrock. A few
86 outliers of Middle Jurassic strata, including Bredon Hill, form isolated hills to the west of the main

87 escarpment. Around Cheltenham, the top of the Cotswold scarp is capped by the Inferior Oolite
88 Group, here dominated by the Birdlip Limestone Formation. This is a thick succession of ooidal
89 limestones which attains a thickness of 110 m around Cleeve Hill and thins rapidly to the south and
90 east (Figure 3). North of Cheltenham, several north-south-trending basin-margin faults step down
91 westwards into the Worcester Basin half-graben. These include the Inkberrow Fault which separates
92 the Bredon Hill and Alderton Hill outliers from the main scarp. Ammonite biostratigraphy provides
93 additional evidence for north-south faulting in the Lower Jurassic Lias Group mudstones at the base
94 of the scarp near Cheltenham (Simms, 1990; Donovan et al., 2005). Further south, around Bath, the
95 stratigraphy is subtly different (Figure 2); the Inferior Oolite Group is much thinner (up to 23 m
96 thick), and the Great Oolite Group caps the main scarp (Barron et al., 2011). The Great Oolite Group
97 comprises the over-consolidated, highly plastic clays of the Fuller's Earth Formation overlain by the
98 massive scarp-forming, ooidal limestones of the Chalfield Oolite Formation, which is up to 35 to 40
99 m thick (Figure 2). The regional dip is about 2° to the south-east, although structures and faults
100 locally modify this.

101 Superficial deposits are largely confined to the river valleys and low ground (Figure 4). A staircase of
102 sand and gravel river terrace deposits is present along a belt 4 km wide either side of the River
103 Severn and the River Avon, whilst parts of the Cheltenham area are covered by sand and gravel
104 deposits of composite solifluction, aeolian and fluvial origin. The southern limit of the Anglian
105 glaciation is inferred to extend into the upper part of the Severn Valley, and extensive glacial
106 deposits occur on the higher ground to the north. The later Devensian glaciation was less extensive
107 and glacial deposits of this age are absent from the lower Severn. Most of the Cotswolds remained
108 unglaciated during both major Quaternary ice advances, but nevertheless exposed to severe
109 periglacial conditions.

110 **Mass movement, cambering, and gull-caves**

111 The interbedded Jurassic limestone and mudstone sequences of the Cotswold Hills are conducive to
112 mass movement. This is particularly evident where river capture has led to greater incision, notably
113 around the city of Bath (Kellaway and Taylor, 1968; Chandler et al., 1976; Hawkins and Privett, 1979;
114 Forster et al., 1987; Hobbs and Jenkins, 2008; Hawkins, 2013) and in the Stroud area. These mass-
115 movements include rotational landslides, together with extensive cambering, valley bulging and gull
116 formation. Cambering and associated phenomena (Figure 5) are caused by the gravitational lowering
117 of outcropping or near-surface strata towards an adjacent valley (Parks, 1991). They occur where
118 competent and permeable rocks overlie incompetent and impermeable beds such as mudstone.
119 Following valley incision, the incompetent material is extruded from beneath the cap-rock, initially
120 as a result of stress relief but also due to a reduction in shear strength due to wetting, drying,
121 decalcification and oxidation (Hawkins, 2013). The overlying competent beds develop a local dip or
122 'camber' towards the valleys due to the loss of support from below, gradually breaking up down
123 slope into more disjointed blocks and draping over the underlying strata (Hollingworth et al., 1944).
124 A valley bulge may develop at the base of the slope due to significant differences in vertical stress
125 between the valley floor and the interfluves. In the competent cap-rocks on the valley flanks or at
126 the crest of the escarpment, gull fractures commonly develop when well-jointed, competent strata
127 become unsupported on their downhill side following mass-movement and valley incision. Extension
128 takes place along joints and bedding planes with bed-over-bed sliding creating voids. When large
129 enough to be explored by cavers, they are termed gull-caves. These are different from normal
130 dissolutionally widened fissures and caves, and can be identified by their distinct morphology. Gulls

131 and gull-caves are typically narrow, parallel-sided, joint orientated rifts, often with symmetrically
132 opposing wall morphologies ('fit features' of Self, 1986), but where there has been vertical as well as
133 lateral movement, bedding planes or other discontinuities may also have parted. A comprehensive
134 review of the theories behind cambering, gull and valley bulge formation has been provided by Parks
135 (1991).

136 Gulls and gull-caves are common throughout the Cotswolds, and are particularly well developed in
137 the Chalfield Oolite Formation around Bath, and in the Birdlip Limestone Formation in the northern
138 Cotswolds (Figure 1). Numerous gulls and well-developed dip-and-fault structures can be observed
139 in many of the old stone mines and quarries in the region, as well as in temporary exposures and
140 construction sites (Hawkins 1980, 2013; Hawkins and Kellaway, 1971; Self, 1986, 1995). Many are
141 well exposed in the extensive stone mines around Bath, especially Box Mine, a suite of complex
142 interlinked pillar-and-stall mines exploiting the Chalfield Oolite Formation, which extends over an
143 area of 6 km² beneath Box Hill near Corsham. Frequent gulls ranging from a few centimetres to over
144 a metre in width and many tens of metres long are present in a zone up to 600 m into the hillside
145 (Self and Farrant, 2013). In the southern part of the mine, thirty-five gulls were recorded along a 200
146 metre transect due east from the entrance, showing an average extension of the strata of just over
147 5% along the length of the passage. The evidence from these mines (Self and Farrant, 2013)
148 indicates that gulls and gull-caves are generally restricted to a zone within a few hundred metres of
149 the valley sides, although exceptionally some gulls may occur up to 0.6 km from the valley margin.

150 The largest gull-caves are developed in the Claverton Gorge east of Bath, around Dursley and Stroud,
151 and in the Cheltenham-Leckhampton area. Detailed descriptions are available in Self and Boycott
152 (1999, 2004, 2005, 2011). Some of these caves are single gull fissures a few metres long, while
153 others form more extensive systems. Many are partially infilled with fallen boulders or sediment.
154 Locally they contain extensive deposits of speleothem, often coating blocks of limestone or sediment
155 infilling the gull and on the gull walls. The longest gull-cave in the Cotswolds is Sally's Rift [ST 794
156 650], situated on the east side of the Avon valley near Bathford. This cave, with a surveyed length of
157 345 metres (Figure 6; Self, 1986, 2008), is a rectilinear network of fissures developed on the
158 dominant local joint directions, 150° (±10°) and 65° (±5°) where cambering has occurred in two
159 divergent directions. The furthest accessible fissure is Far Rift, 60 m from the edge of the hill and (at
160 roof level) around 20 m below the surface. This is a substantial gull, about a metre wide and up to 10
161 m tall. It is well-decorated with calcite speleothem deposits and, at its southern end there are
162 boulders of massive broken speleothem, some of them 0.25 m thick. Further north, gulls and gull-
163 caves occur in the Birdlip Limestone Formation between Wotton-under-Edge in the south and
164 Broadway in the north, often infilled with collapsed boulders or with calcite-cemented sediment and
165 flowstone. Examples include Dead Man's Quarry near Leckhampton (Figure 7), and Coaley Rift Cave
166 [ST 7867 9948] 1 km north of Uley (Self and Boycott, 2004). This is a large rift passage 16 m high and
167 36 m long, divided into several levels by wedged boulders, and containing many speleothems.

168 **Estimating the age of the Cotswold scarp**

169 In the Cotswolds, constraining the age of the escarpment has hitherto been problematic. Whilst
170 glacial deposits and fluvial terraces, where they exist, provide an indication of the age of the valley
171 floor, they do not constrain the age of the erosional topography or provide evidence for how the
172 valley morphology develops. There are no talus flatirons that can be dated. Dating the age of the
173 landslides can provide some indication of the age of mass-movement, and thus by implication the

174 age of the back-scarp feature. Based on slope sections and Holocene alluviation, Privett (1980)
175 postulated that no new large-scale, deep-seated landslides have occurred in the area since the
176 Devensian glaciation. Rotational slides of moderate size and small scale shallow mudslides have
177 occurred in recent times, but usually as re-activations of existing slides in association with the
178 construction of roads, landscaping, and retaining structures (Forster et al., 1987; Hawkins, 2013).
179 Hutchinson and Coope (2002) obtained a minimum age for a mass movement valley bulge feature by
180 dating overlying fluvial gravels. The bulge, exposed in a dam cut-off trench at the Dowdeswell Dam
181 [SO 988 198], near Cheltenham is covered by later gravels which have been assigned to the Younger
182 Dryas period. Similar spreads of quartzose sand and ooidal limestone gravel, known as the
183 Cheltenham Sand and Gravel, occur at the foot of the scarp around Cheltenham and north to Bredon
184 Hill (Figure 4). These are thought to be composite solifluction and aeolian deposits ('head') of
185 Devensian age (Barron et al., 2002).

186 In this study we have used the age of speleothems preserved in gull-caves to constrain the age of the
187 Cotswold escarpment. As the opening of these caves is conditional on valley incision and mass-
188 movement, speleothems within them must be younger than the scarp. To determine the age and
189 rate of retreat of the Cotswold escarpment, speleothem samples were collected from a number of
190 gull-caves across the region, both on the scarp edge and from sites flanking incised valleys. Care was
191 taken to obtain clean, dense crystalline in-situ speleothem material, focussing on older deposits
192 where it was feasible to determine a stratigraphy. Samples were prepared and analysed at the NERC
193 Isotope Geosciences Laboratory at the British Geological Survey in Keyworth. Material from along
194 single growth horizons was extracted using a dental drill fitted with a diamond-encrusted cutting bit,
195 avoiding recrystallised, corroded or porous material and hiatuses. Where possible, the basal growth
196 layer of each speleothem was sampled, as it is the basal age of the oldest speleothem that provides
197 a minimum age estimate for the cave. By contrast, younger speleothem deposits do not constrain
198 the timing of gull-cave formation, only the timing of drip-water recharge. Where the speleothem
199 was thick enough, two samples were dated to check for stratigraphic consistency. Details of the
200 analytical protocols used are given in Douarin et al., (2014) and briefly summarised here. The
201 subsamples were dissolved in high purity HNO₃, and spiked with a mixed ²²⁹Th/²³⁶U tracer. No silicate
202 detritus was observed and so further treatment with HF-HNO₃-HClO₄ to ensure total dissolution was
203 not required. After sample/spike equilibration, U and Th were co-precipitated with Fe-hydroxides,
204 and further purified and separated by ion exchange ready for mass spectrometry following Edwards
205 et al., (1988) with modifications. U and Th isotope ratios were measured on a Thermo Scientific
206 Neptune Plus multicollector ICP mass spectrometer in dry plasma mode fitted with a Cetac Aridus II
207 desolvating nebulizer fitted with an ESI PFA Teflon low-uptake rate nebulizer tip. Uranium series
208 isotope ratios and ages are presented in Table 1 and Figure 8. Activity ratio data were calculated
209 from measured atomic ratios and the ²³⁴U and ²³⁰Th decay constants (see Cheng et al., 2000).
210 Uncertainties are quoted at the 2 sigma level (percent or absolute as indicated). Correction for
211 detrital Th contributions was made using an average continental detritus composition of [²³²Th/²³⁸U]
212 = 1.2 ± 0.6, [²³⁴U/²³⁸U] = 1.0 ± 0.5 and [²³⁰Th/²³²Th] = 1.0 ± 0.5. The U series data (Table 1) show that
213 the gull-cave speleothems record carbonate deposition over a large age range, between 49.5 ± 0.5
214 ka and 346 ± 19.3 ka. Younger speleothems are almost certainly present, but not sampled or dated.
215 Associated with these ages is also a range in relative magnitude of the age uncertainties. These fully
216 propagated uncertainties are controlled primarily by the model detrital Th composition and
217 magnitude of the required correction. The effect of applying the detrital correction is illustrated by

218 comparing uncorrected and corrected ages and their associated uncertainties, and is mainly
219 significant for samples where $[^{230}\text{Th}/^{232}\text{Th}]$ is less than ~ 20 . The source of detrital Th likely derives
220 from small amounts of limestone substrate incorporated into new growth speleothem. Initial
221 $[^{234}\text{U}/^{238}\text{U}]_i$ are mainly close to secular equilibrium (~ 1) and unremarkable, although BR39 has
222 $[^{234}\text{U}/^{238}\text{U}]_i = \sim 0.84$ suggesting a source that had been subjected to prior U-removal.

223 The basal U-series ages obtained here, together with a c. 250 ka age reported for calcite-cemented
224 rubble infilling gull-fissures from a road cutting near Bath University (Hawkins, 2013), and two alpha-
225 spectrometric U-series dates of >350 ka from Sally's Rift (Self, 1995), indicate that all the gull-caves
226 were open prior to the last interglacial (MIS 5). In the case of Sally's Rift, Dead Man's Quarry and
227 Catbrain Quarry, the oldest dates (346 ± 19 ka, 348 ± 15 ka, and the less precise 320 ± 74 ka),
228 overlap within uncertainty with the MIS 9/10 boundary at c. 337 ka (Lisiecki and Raymo, 2005), and
229 thus predate most of the fluvial terraces exposed in the valley floor. As gull-caves do not generally
230 occur more than a few hundred metres from the hillside, the U-series dates indicate that the scarp
231 edge or valley side has remained in the same approximate location over the last ~ 350 ka, a rather
232 surprising conclusion given the present instability of the scarp face (Hawkins, 2013).

233 Assuming a conservative distance of gull formation of 0.5 km from the scarp edge, the basal U-series
234 dates from scarp-edge gull-cave speleothems around Cheltenham, at Dead Man's Quarry and
235 Catbrain Quarry, suggest that the rate of scarp retreat over the past ~ 350 ka (i.e. over more than
236 one glacial-interglacial cycle) is at most about 1.42 m ka^{-1} . A more realistic upper value of c. 0.57 m
237 ka^{-1} can be estimated if the cambering and gulls were formed within 200 m of the escarpment, which
238 is typically what is observed from quarry sections and old mine workings (Self and Farrant, 2013).
239 Clearly, these rates should be treated as maximum values, as speleothem deposition may be
240 initiated a significant time after gull formation. These values are comparable with rates of 0.12 to
241 1.23 m ka^{-1} for Lateglacial and Holocene rock-wall retreat rates on Mynydd Du, a Devonian
242 sandstone escarpment in South Wales (Curry and Morris, 2004), 0.10 - 0.75 m ka^{-1} from Lateglacial
243 and Holocene basalt cliffs in Trotternish, Scotland (Hinchliffe and Ballantyne, 1999) and 0.37 m ka^{-1}
244 for a sandstone scarp in Ethiopia (Nyssen et al., 2006) from estimates of annual rock-fall volume.
245 Schmidt (1988) documented similar retreat rates from a number of different cuesta scarps in the
246 Atlas Mountains of Morocco by dating talus relics or sediments in the scarp foreland, or by dating
247 relict gravels on the cuesta back-slope. These values averaged 1.3 m ka^{-1} for weak Mio-Pliocene
248 conglomeratic cap-rocks and 0.5 m ka^{-1} for more resistant and thicker Palaeogene and Cretaceous
249 limestone cap-rocks analogous to the Jurassic limestones of the Cotswolds. Schmidt (1989) also
250 obtained rates of 0.5 to 6.7 m ka^{-1} for Cretaceous scarps on the Colorado Plateau, whilst Cole and
251 Mayer (1982) estimated a rate of retreat of 0.45 m ka^{-1} for the Redwall Limestone in the Grand
252 Canyon.

253 The dates from the sites within the deeply incised river valleys around Bath, notably Sally's Rift,
254 indicate that the Avon Valley had incised through the Chalfield Oolite and a significant distance into
255 the underlying Fuller's Earth mudstone in order to initiate cambering and gull formation prior to MIS
256 9 (c. 350 ka). The rate of valley incision cannot be determined with any accuracy as the depth of the
257 valley when cambering was initiated is unknown, as is the time lapse between gull formation and
258 speleothem deposition. However, based on the elevation of the cave, it must be less than c. 0.42 m
259 ka^{-1} . Similarly, a pre-MIS 5 date is given for the main cambering event at Bath by Chandler et al.,

260 (1976). By inference, the capture of the Thames headwaters by the River (Bristol) Avon was
261 complete by this time (Self, 1995).

262 **Models of valley incision and scarp formation**

263 The evidence for the Pleistocene incision of the Severn valley is recorded in a range of superficial
264 deposits (Figure 4). The area lies beyond the limit of the Devensian glaciation (MIS 2), but the
265 presence of glacial and glaciofluvial deposits including the Wolston Glacigenic Formation (Barron et
266 al., 2002) demonstrate that the southern margin of the Anglian ice-sheet (MIS 12) impinged on the
267 northern part of the area. River terrace deposits are associated with the Severn and Avon rivers.
268 They fall into two formations, the Severn Valley Formation (Maddy et al., 1995) and the
269 Warwickshire Avon Valley Formation (Figure 9). Both comprise six "terrace" members which are
270 dominated by fluvial sand and gravel deposited during cold-stage conditions, plus Holocene
271 alluvium. These terraces have been dated through a mixture of biostratigraphical evidence, an
272 amino acid geochronology, together with marker inputs from three different glaciations (Bridgland
273 et al., 2004). They record the progressive incision of the River Severn and its tributaries during the
274 Middle to Late Pleistocene. The highest fluvial terrace (the Spring Hill Member) is about 50 m above
275 the present day floodplain and is provisionally correlated with MIS 10. West of the Malverns, an
276 outcrop of pre-Anglian sand and gravel (the Mathon Sand and Gravel Formation) associated with a
277 buried palaeovalley (Barclay et al., 1992) is attributed to the Mathon palaeo-river (Coope et al.,
278 2002). Maddy (2002) suggests that although the timing of terrace aggradations are climatically
279 controlled, the long-term incision of the River Severn appears to be driven by crustal uplift. Based on
280 this data, Maddy (2002) calculated a long-term time-averaged incision rate of 0.15 m ka^{-1} over the
281 past 400 ka, using the base of the terrace deposits, although rates varied spatially and temporally.
282 However, subsequent to the Anglian glaciation, much of this incision has been restricted to a zone
283 close to the present River Severn, with the present channel occupying a relatively narrow floodplain
284 (typically <2 km wide) incised up to 10-15 m into the floor of a much wider (10-20 km) valley. This
285 may reflect a shift in the style of terrace aggradation during the Mid-Pleistocene revolution when
286 climatic fluctuations shifted from 41 ky Milankovitch cycles to stronger 100 ky cycles (Bridgland and
287 Westaway, 2008). This shift led to a change from weak terrace aggradations deposited over several
288 short 41 ky cycles to a period of greater incision and the development of well defined, 100 ky single-
289 cycle terraces.

290 Whilst the glacial and river terrace deposits clearly demonstrate that the Severn valley was
291 excavated to a significant depth prior to the Anglian glaciation, they do not clarify the style of valley
292 excavation due to their restricted geographical extent. Are the Severn valley and its flanking
293 escarpments a result of scarp retreat or differential erosion – back-stripping or down-wearing
294 (Figure 10)? Combining the rate of valley incision with the rate of scarp retreat derived from U-series
295 dating of gull cave speleothems permits the relative amount of lateral versus vertical erosion to be
296 constrained. The rate of scarp retreat derived from speleothem data is inconsistent with that of
297 valley incision. To generate the present relief of about 300 m using incision rates of 0.15 m ka^{-1}
298 calculated by Maddy (2002) would take about 2.0 Ma. However, the limestone scarp would have
299 only retreated by about 0.56 – 2.84 km in this time, far short of the 10-20 km width of the present
300 valley. Rates of past scarp retreat or valley incision would have to be radically different to achieve
301 the current valley morphology. We suggest the location of the Cotswold escarpment is more likely to
302 be due to lithological (and thus erosional) heterogeneity. If so, it might be expected that facies and

303 thickness variations in the more resilient cap-rock would be a significant influence on resulting
304 surface topography. However, there is little gross lateral and vertical variability in the predominantly
305 limestone succession of the Inferior Oolite Group (see e.g. Barron et al., 2002) and an isopachyte
306 map of the group (Figure 3) across the Cotswolds shows that it reaches its maximum thickness (110
307 m) in the Cleeve Hill area near Cheltenham, close to the present scarp edge. Clearly the scarp here is
308 not a consequence of the westward thinning of the Inferior Oolite. However, another possibility is
309 that the present location of the escarpment may be a consequence of the prior removal of the
310 Inferior Oolite to the west by a pre-Quaternary erosion surface.

311 Across much of Southern England, a regional unconformity is present at the base of the Lower
312 Cretaceous. In early Aptian times, the cessation of active crustal extension in the Wessex Basin
313 coincided with the end of a protracted period of erosion (Ruffell, 1992). Across southern England,
314 Aptian and Albian strata - the Upper Greensand and Gault formations - transgressed across the
315 erosion surface, overlapping the faulted basin margins to rest unconformably upon Palaeozoic rocks
316 of the London Platform and south-west England. In south-west England, this unconformity oversteps
317 Jurassic and Triassic strata to rest on Permian rocks on the Haldon Hills at an elevation of 190-200 m
318 (Hancock, 1969). Recent evidence from the Mendip Hills (Farrant et al., 2014) at Tadhil, 25 km south
319 of Bath, demonstrates that the Upper Greensand Formation oversteps the Jurassic strata to rest on
320 Palaeozoic bedrock (Silurian volcanics and Devonian sandstone) at an elevation of c. 280 m (Figure
321 1). Given the palaeogeography during the latest Albian (Cope et al., 1992), this erosion surface
322 almost certainly extended across the area of the Cotswolds and Severn Valley, bevelling across the
323 Middle and Upper Jurassic strata. Ruffell (1992) suggests up to 75-100 m of early Albian Gault Clay
324 extended across this region. Circumstantial evidence of a former Cretaceous cover in this area is
325 offered by the presence of flint scatters across the Cotswolds (although possibly of anthropogenic
326 origin) derived from the Upper Cretaceous Chalk Group. Flints and possible Upper Greensand chert
327 occur in high level gravel deposits resting on the Great Oolite around Bath (Donovan, 1995).
328 Although reworked and probably of Quaternary age, these gravels may have been derived from a
329 former Cretaceous cover. Similar deposits also occur in Sally's Rift (Self, 1995) and can be seen in
330 some of the gulls exposed in old stone mines in the area.

331 The subsequent removal of this Cretaceous cover across Southern England during the Neogene
332 revealed a lithologically variable Jurassic and Lower Cretaceous succession. Initially consequent
333 rivers and streams following the main northwest to southeast drainage alignment in southern
334 England, parallel to the regional tilt of the landmass (Gibbard et al., 2013), were superimposed onto
335 the older bedrock. These drainage systems gradually became reoriented to the underlying geological
336 structure through the effects of multiple glaciations and variable erosion rates, allowing the more
337 resistant lithologies to form uplands. The generalised, gently sloping topographic summit surface on
338 the Cotswolds, which also extends across to the Forest of Dean (Donovan et al., 2005), may be a
339 residual effect of the former extent of the Cretaceous cover. A similar, more pronounced erosion
340 surface is developed further south on the steeply dipping Carboniferous limestones in the Mendip
341 Hills where it forms a conspicuous plateau at around 260-280 m asl.

342 Under this proposed scenario, the disposition of the Jurassic rocks, formerly at subcrop beneath the
343 Cretaceous unconformity surface, is inferred to control the location of the present escarpment.
344 Where the harder limestone units were present at subcrop, subsequent denudation would leave
345 these areas upstanding whilst the softer mudrocks would be eroded more rapidly. This denudational

346 lowering is likely to be most effective on the less indurated Triassic and Jurassic mudrocks which are
347 particularly susceptible to periglacial effects (Simms, 2004; Murton and Belshaw, 2011), especially
348 during the cold conditions predominant during the Pleistocene. Superimposition of the drainage
349 pattern of the former Cretaceous cover would have also played a role in shaping the relief, possibly
350 helping to create some of the major wind gaps and vales. Concomitant hillslope processes,
351 landsliding and incision by tributary valleys cutting into the upstanding resistant rock-mass would
352 serve to modify the scarp-edge, creating the indented feature we see today. This scenario also
353 explains how the Cotswold Hills are able to maintain their elevation despite limestone denudation
354 rates (predicted from solute concentrations at springs; Goudie, 1990) suggesting that such limestone
355 scarps could not persist for more than one or two million years (Simms, 2004). The presence of a
356 protective siliciclastic Cretaceous cover served to protect the Jurassic limestones from dissolution
357 until relatively recently. There is evidence that some dissolutional lowering has occurred as
358 limestone outcrops towards the scarp edge are more dissected than those further down dip,
359 suggesting more prolonged exposure near the scarp edge. Subsequent flexural unloading due to the
360 erosion of the weak mudrocks in the Severn Valley may have caused uplift of the valley flanks (Watts
361 et al., 2000). This only serves to enhance the relief generated by the large scale removal of softer
362 rock beneath the sub-Cretaceous unconformity. Lane et al., (2008) suggest denudational isostasy
363 may have contributed up to about 50% of the present-day Cotswolds' relief.

364 In this model, the distance the scarp has retreated is predicted to be much less than the valley width
365 (Figure 10). If this model is correct, then the initial position of the Cotswold escarpment, as
366 represented by the position of the base of the Inferior Oolite Group at the unconformity subcrop in
367 the Cheltenham area, and the base of the Great Oolite Group around Bath, can be estimated by
368 extrapolating the base of these limestone units up-dip to where they would have intersected the
369 unconformity surface. To determine the geological structure, the base of the Inferior Oolite Group
370 around Cheltenham (here the Birdlip Limestone Formation) was modelled using GSI3D software
371 (Kessler et al., 2009). Data from borehole logs, 1:50 000 scale geological map data and the
372 NEXTMap™ Britain Digital Terrain Model (DTM) produced by Intermap Technologies were used to
373 construct a series of geological cross sections from which a geological fence diagram was produced.
374 A triangulated irregular network (TIN) surface was then calculated based on mathematical
375 interpolation between the nodes along the drawn sections and the limits of the units, smoothed and
376 contoured (Figure 11). Similarly, the maximum topographic 'summit' surface which approximates to
377 the sub-Cretaceous erosion surface was derived from analysis of the 5 m NEXTMap™ Britain DTM.
378 To achieve this, the highest elevations on a 2 km x 2 km grid were extracted from the DTM and
379 modelled as a TIN surface using the 3D Analyst ArcToolbox (ArcGIS 10.1, ESRI). A planar surface —
380 modelling the regional topographic trend —was subsequently merged with the TIN surface to create
381 a generalised Cotswold summit surface extending up-slope to the west beyond the present scarp
382 (Figure 12).

383 The two surfaces are also shown in a series of cross-sections (Figure 13), and clearly show that the
384 plateau surface dips at a lower angle than the regional stratigraphic dip of $<1^\circ$ to the southeast.
385 Extrapolation of these two surfaces west beyond the present escarpment suggests that the base of
386 the Inferior Oolite Group intersects the postulated sub-Cretaceous erosion surface within about 2 to
387 5 km of the present escarpment edge. This amount of scarp retreat, based on the minimum rate
388 predicted from gull-cave speleothems, accords well with timescales of valley incision in the lower
389 Severn valley determined by Maddy (2002). The clear anomaly though is Bredon Hill, an outlier of

390 the Birdlip Limestone which lies 10 km from the present scarp and reaches an elevation of 299 m asl.
391 However, this is separated from the main outcrop by a significant fault, the Inkberrow Fault which
392 downthrows the strata to the west. It is probable that this faulting produced an isolated outlier of
393 the Inferior Oolite Group beneath the sub-Cretaceous erosion surface, which subsequently was left
394 upstanding by the denudation of the surrounding mudstone. Similarly, the large Inferior Oolite
395 outlier on Dundry Hill south of Bristol lies on a synclinal axis. This syncline is inferred to have
396 preserved the Inferior Oolite Group beneath the Cretaceous unconformity whilst in the surrounding
397 area it was removed by intra-Cretaceous erosion. In the north-east of the region, the Inferior Oolite
398 Group thins rapidly to the east across the Vale of Moreton axis (which is the manifestation at the
399 surface of the system of faults forming the eastern margin of the Worcester Basin). The lower part of
400 the Group including the Birdlip Limestone was removed by intra-Bajocian erosion. This structure
401 causes the base of the Inferior Oolite Group to rise up and intersect the sub-Cretaceous erosion
402 surface, allowing subsequent denudation to generate a second east-facing escarpment, creating the
403 Vale of Moreton.

404 **Conclusions**

405 Erosional landforms such as the valley margins and escarpments have traditionally been hard to date
406 due to the lack of datable deposits associated with them. Dating speleothems contained in mass-
407 movement gull-caves is a new technique which can be used to estimate the minimum age of an
408 escarpment and determine maximum rates of scarp retreat, and which is applicable wherever gull-
409 caves are present. The application of this methodology to the lower Severn valley and the Cotswold
410 Hills, combined with data from fluvial terraces and other superficial deposits has enabled a better
411 model of regional landscape evolution to be deduced. The data obtained from gull-caves
412 demonstrates that the Cotswold escarpment has retreated less than 0.5 km during the last c. 350 ka.
413 Given rates of valley incision determined from fluvial terraces along the River Severn and scarp
414 retreat rates determined from these gull-caves, we suggest that valley widening by scarp retreat was
415 not the dominant process in the development of the regional topography. Instead, we propose that
416 the relief is generated by differential erosion of the heterogeneous bedrock succession, enabling the
417 Cotswold escarpment to develop 'in situ'. The present location of the scarp is most probably
418 controlled by the exhumation of more resistant ooidal limestone units from beneath a sub-
419 Cretaceous unconformity. Modelling of topographic and bedrock surfaces in the Cheltenham area
420 suggests that the Cotswold scarp has retreated less than 5 km since these rocks were exhumed, and
421 that the outliers of Middle Jurassic strata such as Bredon Hill and Dundry Hill are preserved as
422 downthrown fault blocks or in synclinal axes.

423 **Acknowledgments**

424 We would like to thank the reviewers for constructive reviews which helped improve this paper.
425 Farrant, Noble, Barron, and Grebby publish with the approval of the Executive Director of the British
426 Geological Survey. Mr. Neil Boulton and Dr. Diana Sahy of NIGL are thanked for their assistance with
427 U-series sample preparation and chemistry.

590 **Figures:**

591 **Figure 1.** Geological map of the Cotswold Hills region, England. Known gulls and gull-caves are shown
592 as circles, whilst gull-caves which have been dated in this study are shown as stars. NEXTMapTM
593 Britain elevation data from Intermap Technologies. See the online version for a colour version.

594 **Figure 2.** Geological section through the Jurassic sequence in the Cheltenham area (A) and around
595 Bath (B) showing the differences in local stratigraphy.

596 **Figure 3.** Isopach map of the Inferior Oolite Group in the Cotswold Hills (modified from Green, 1992,
597 fig. 27). Contours are in metres.

598 **Figure 4.** Superficial deposits in the Cotswold region, including river terrace deposits in the Severn,
599 Warwickshire Avon and upper Thames valleys, and glacial till in the north and west. Orange areas
600 are river terraces, blue and pink are glacial and glaciofluvial sediments respectively and yellow
601 alluvium. The red line marks the inferred limit of the Anglian glaciation, whilst the blue is the limit of
602 the Devensian glaciation. NEXTMap™ Britain elevation data from Intermap Technologies. See the
603 online version for a colour version.

604 **Figure 5.** Section through an idealised Cotswold hillslope showing major features of cambering, gull
605 formation and valley bulge.

606 **Figure 6** Survey of Sally's Rift and other caves in Gully Wood (after Self, 1986). Speleothem samples
607 were collected from the southern end of Far Rift.

608 **Figure 7.** Dead Man's Quarry, Leckhampton, looking west [SO 9464 1772]. The cliff face in the Birdlip
609 Limestone clearly displays numerous vertical gull fractures, from one of which a speleothem sample
610 was obtained. The main Cotswold escarpment is located less than 200 m behind the far end of the
611 quarry.

612 **Figure 8.** Isochrons for the U-series samples from the Cotswold gull caves.

613 **Figure 9.** Idealised transect through the Severn–Avon terrace sequence. Severn nomenclature is
614 applied where possible. Correlations with the marine isotope record are indicated. Modified from
615 Bridgland et al. (2004).

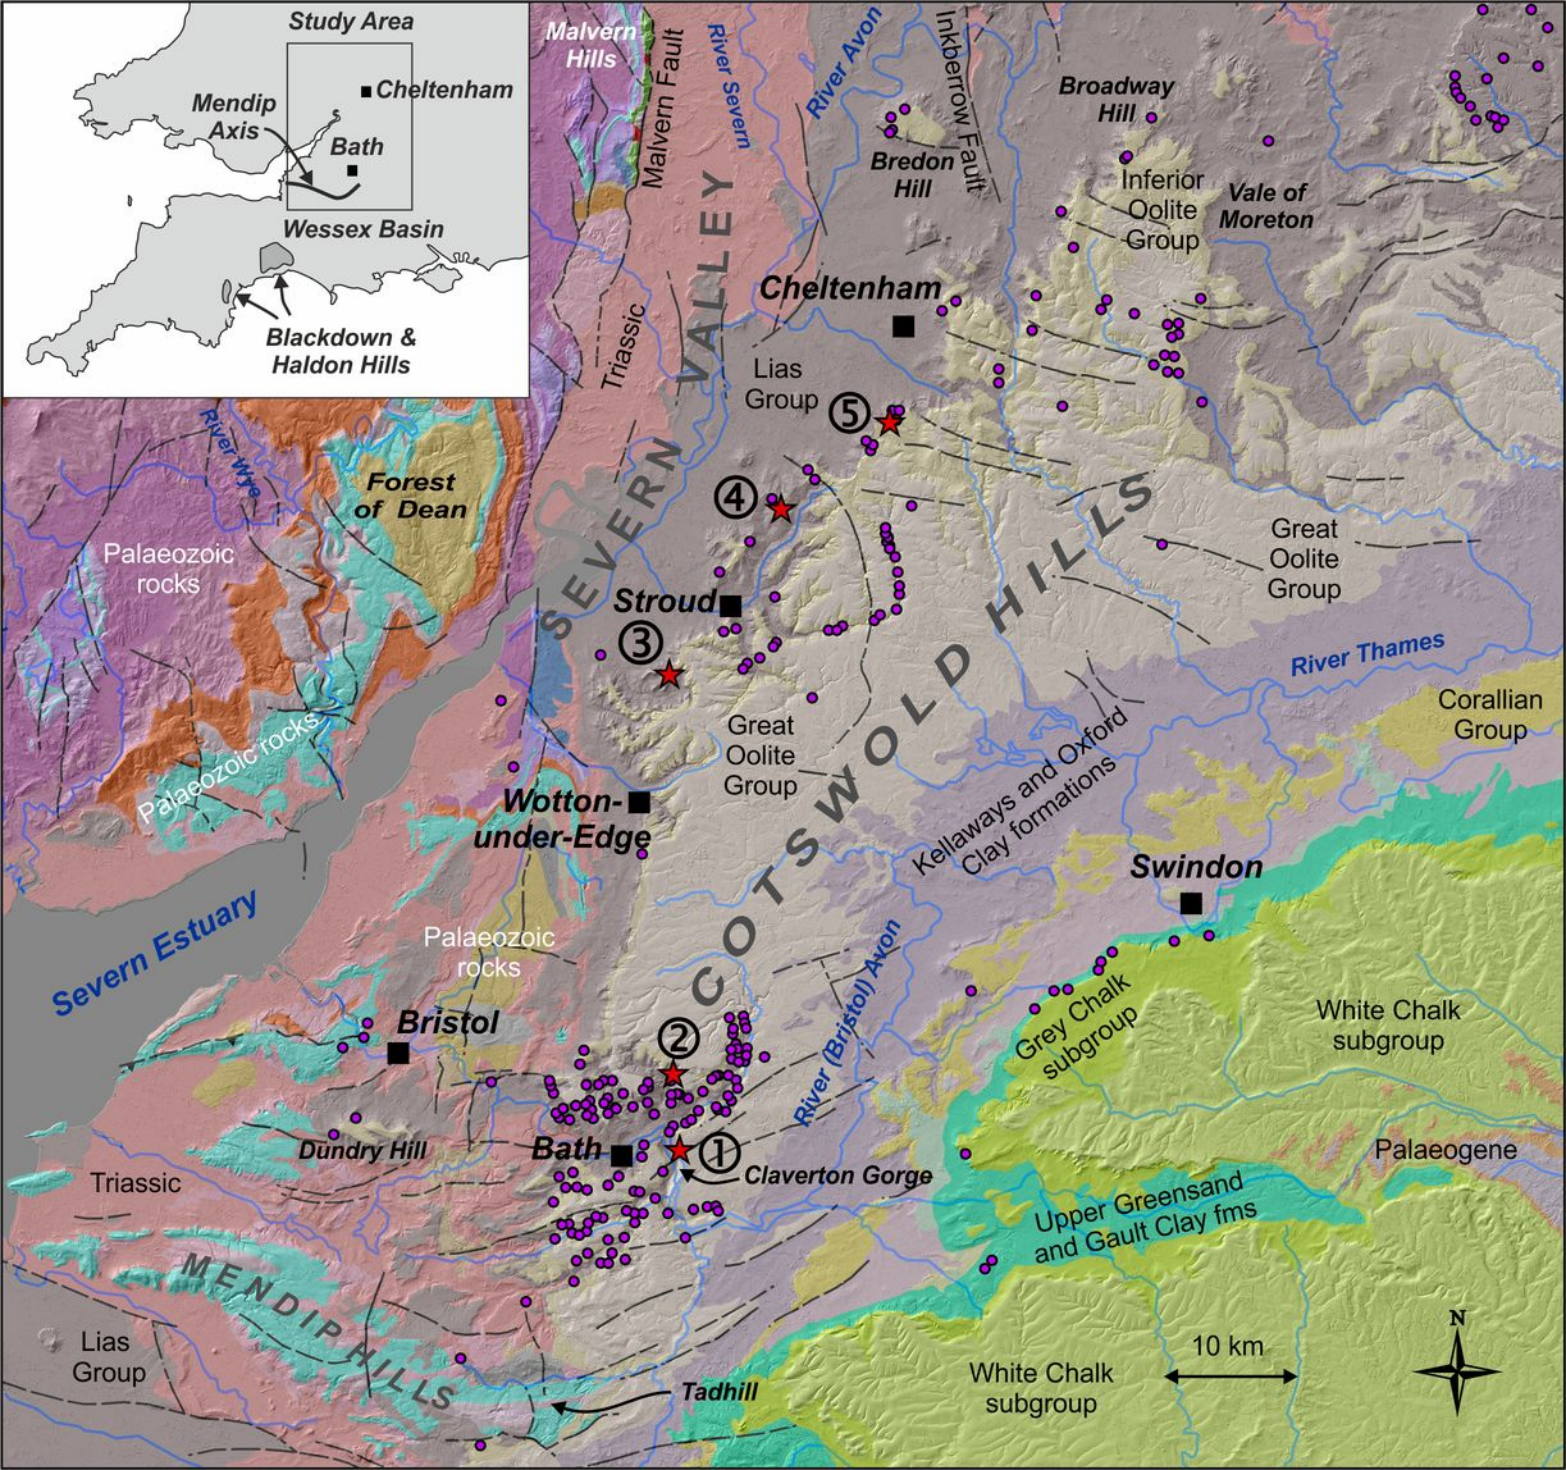

616 **Figure 10.** Cross sections across the Severn valley and the Cotswold escarpment under different
617 models of landscape evolution. A. Valley cross section derived by valley incision and widening in
618 response to fluvial incision, lateral channel migration and hillslope retreat at times $t = 1-4$. B.
619 Topography derived by differential erosion beneath a sub-Cretaceous unconformity at times $t = 1-4$.

620 **Figure 11.** Generalised contours (metres above sea-level) for the base of the Inferior Oolite Group
621 (Birdlip Limestone Formation) in the northern Cotswolds, based on 3D geological modelling. The
622 steep dips along the southern margin of the model are an artefact of the model boundary. The
623 locations of the cross sections shown in Figure 13 are shown. Base map contains Ordnance Survey
624 data © Crown Copyright and database rights 2014. See the online version for a colour version.

625 **Figure 12.** Generalised contours for the Cotswold summit surface in the northern Cotswolds
626 superimposed on the modelled base Inferior Oolite Group and extended across the Severn valley.
627 Base map contains Ordnance Survey data © Crown Copyright and database rights 2014. See the
628 online version for a colour version.

629 **Figure 13.** Cross sections across the northern Cotswolds, showing the disparity between the
630 Cotswold Summit surface (purple) and the base of the Inferior Oolite Group (Birdlip Limestone
631 Formation – blue). Location of the sections is shown in Figure 11. See the online version for a colour
632 version.

633 **Table 1.** U-series and age data for speleothem samples collected from the gull-caves along the
634 Cotswold escarpment and in the Avon valley.

A Cheltenham area

B Bath area

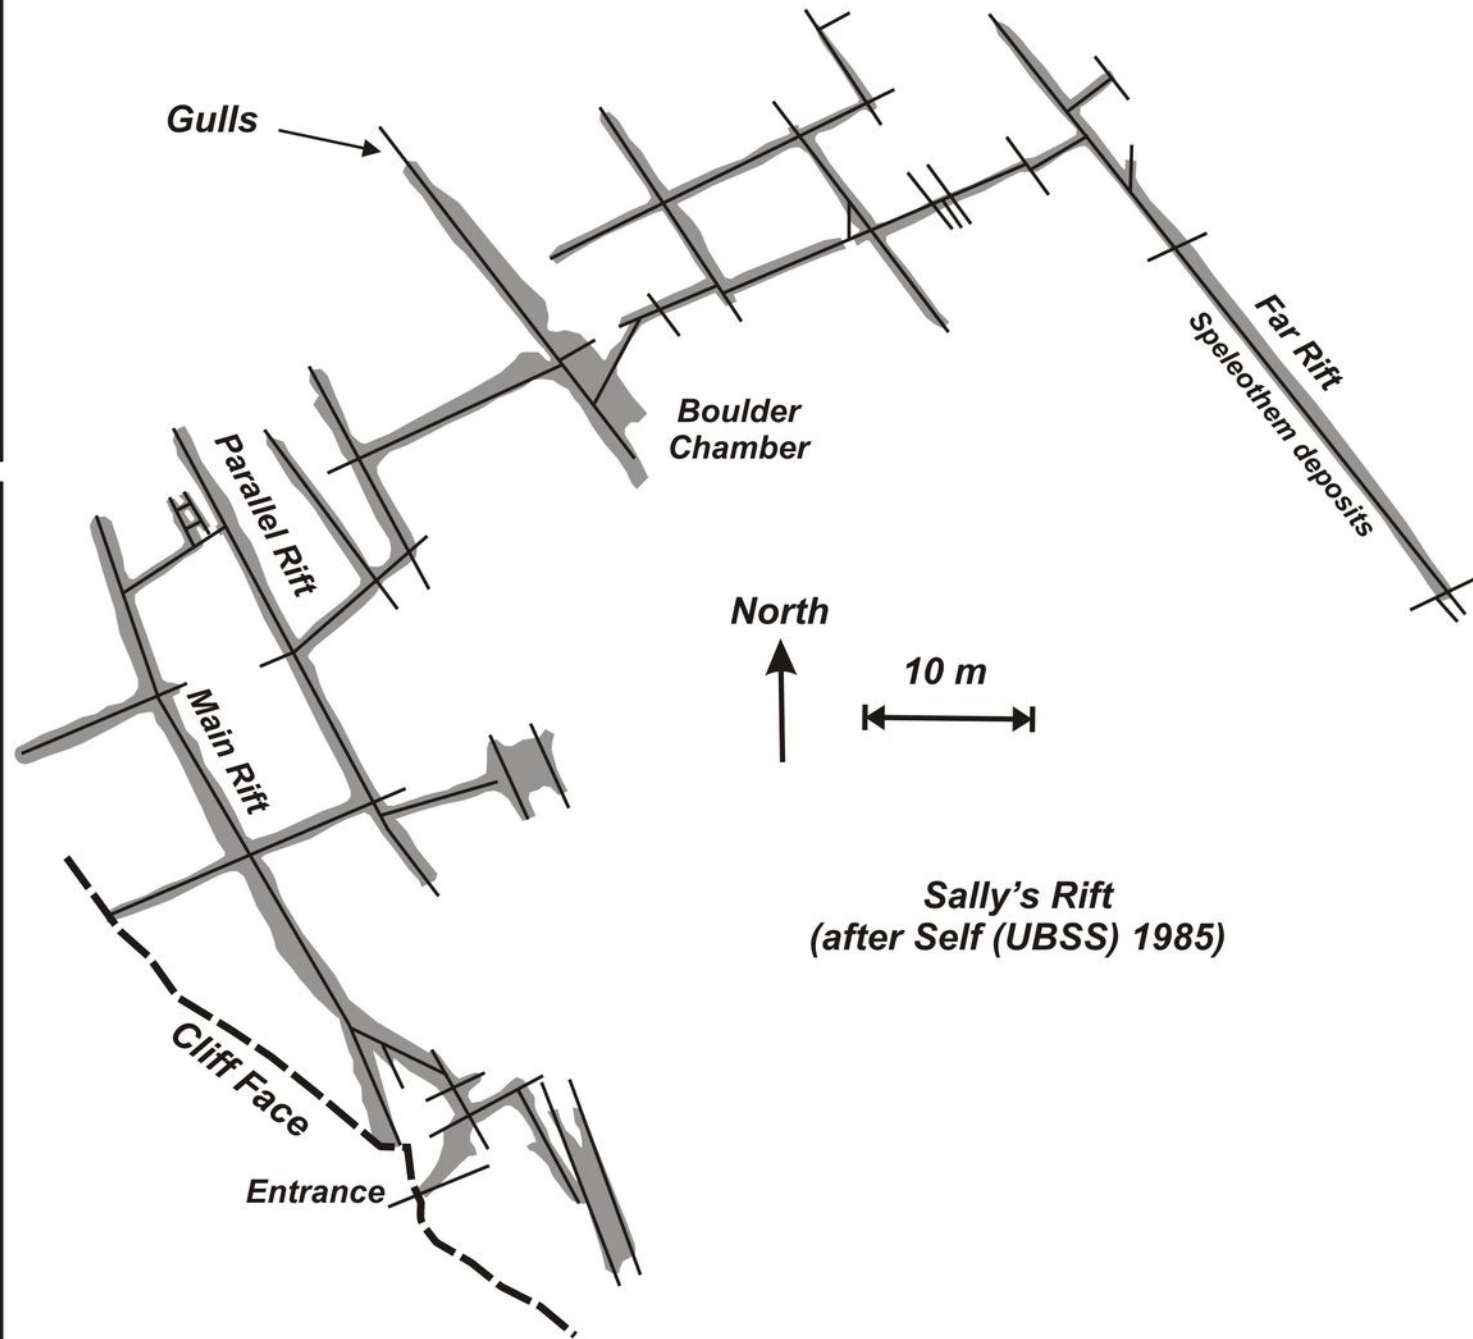

Gully Wood Cave No. 5
(after Self (UBSS) 1999)

Gully Wood Cave No. 4
(after Self (UBSS) 1999)

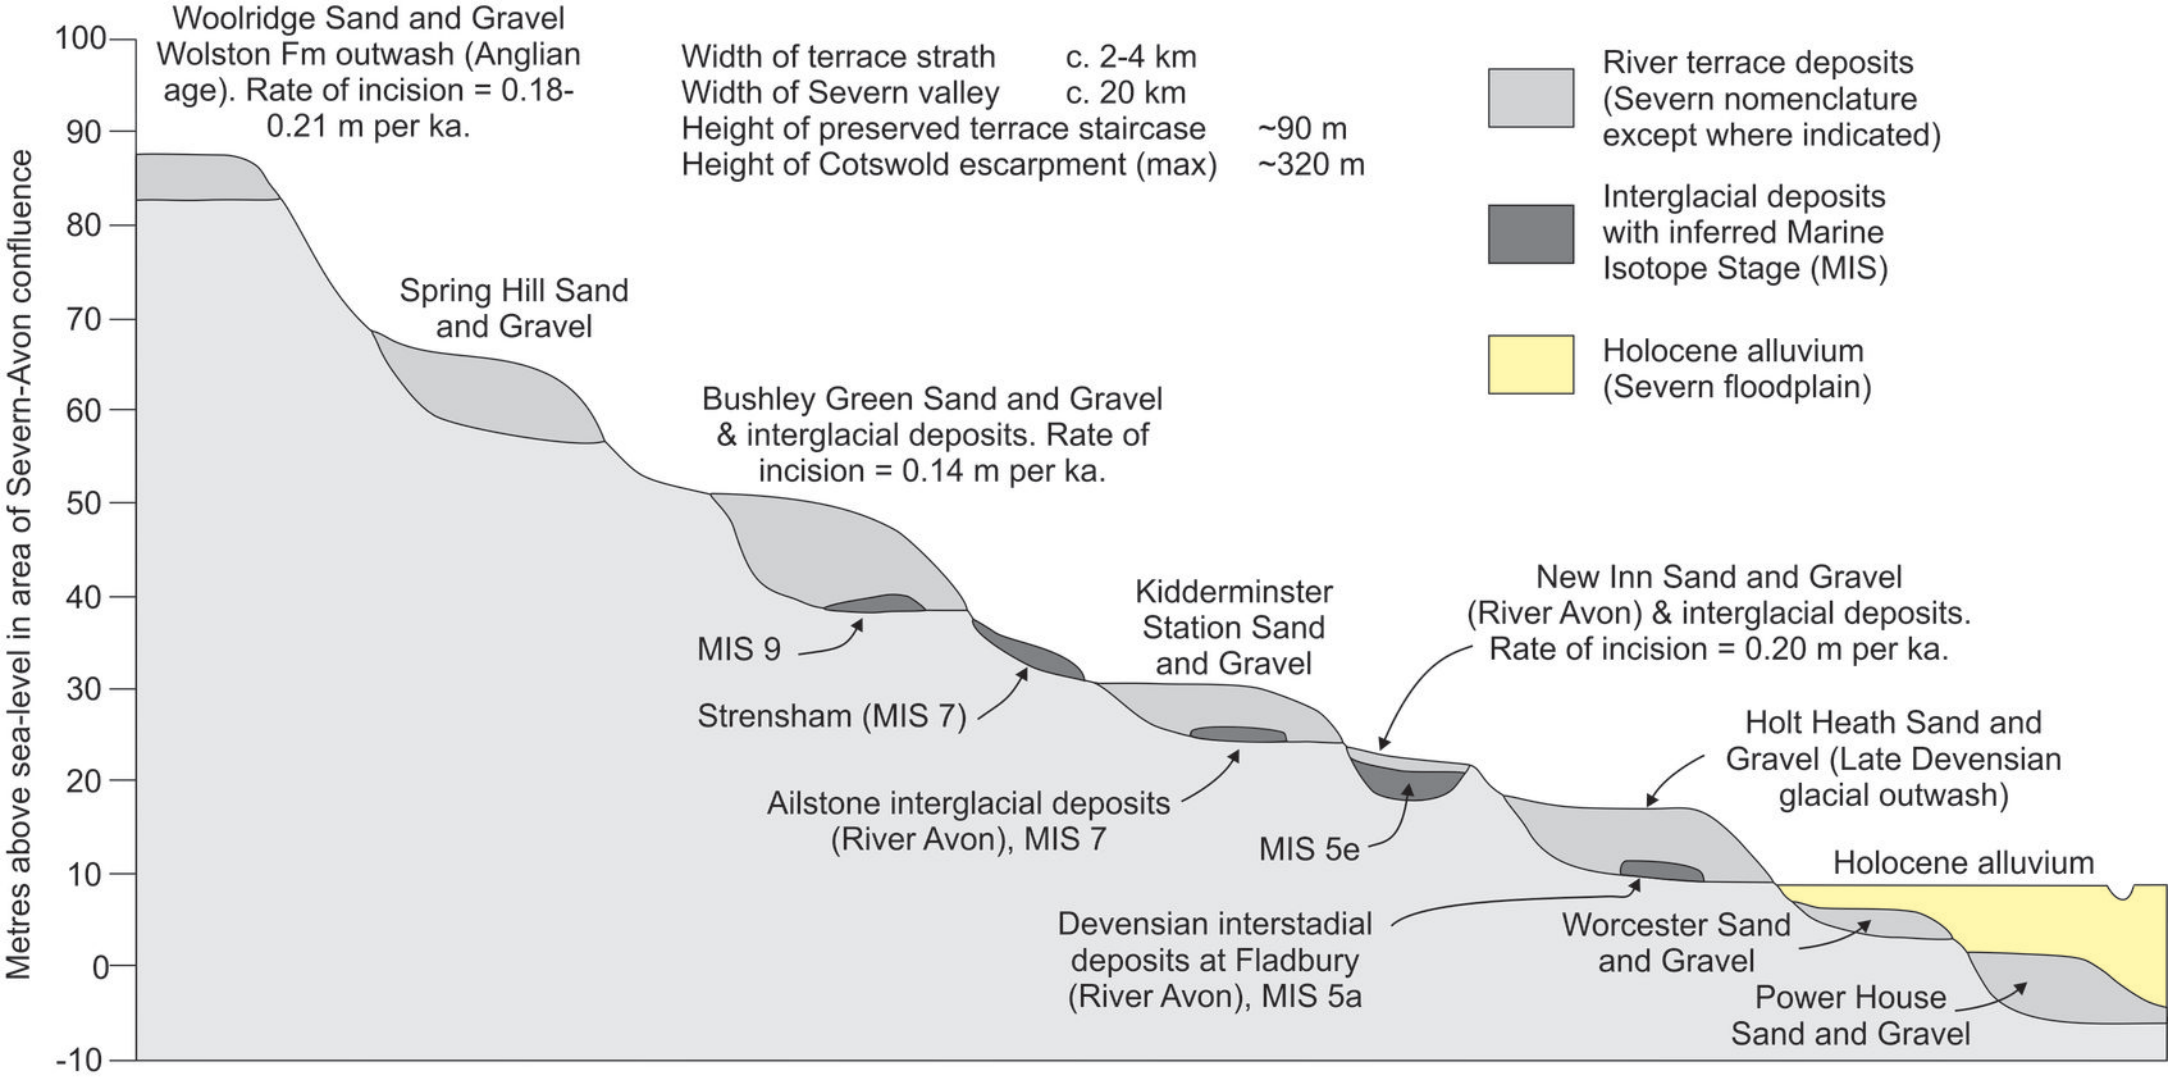

Sally's Rift
(after Self (UBSS) 1985)

A. Model 1.

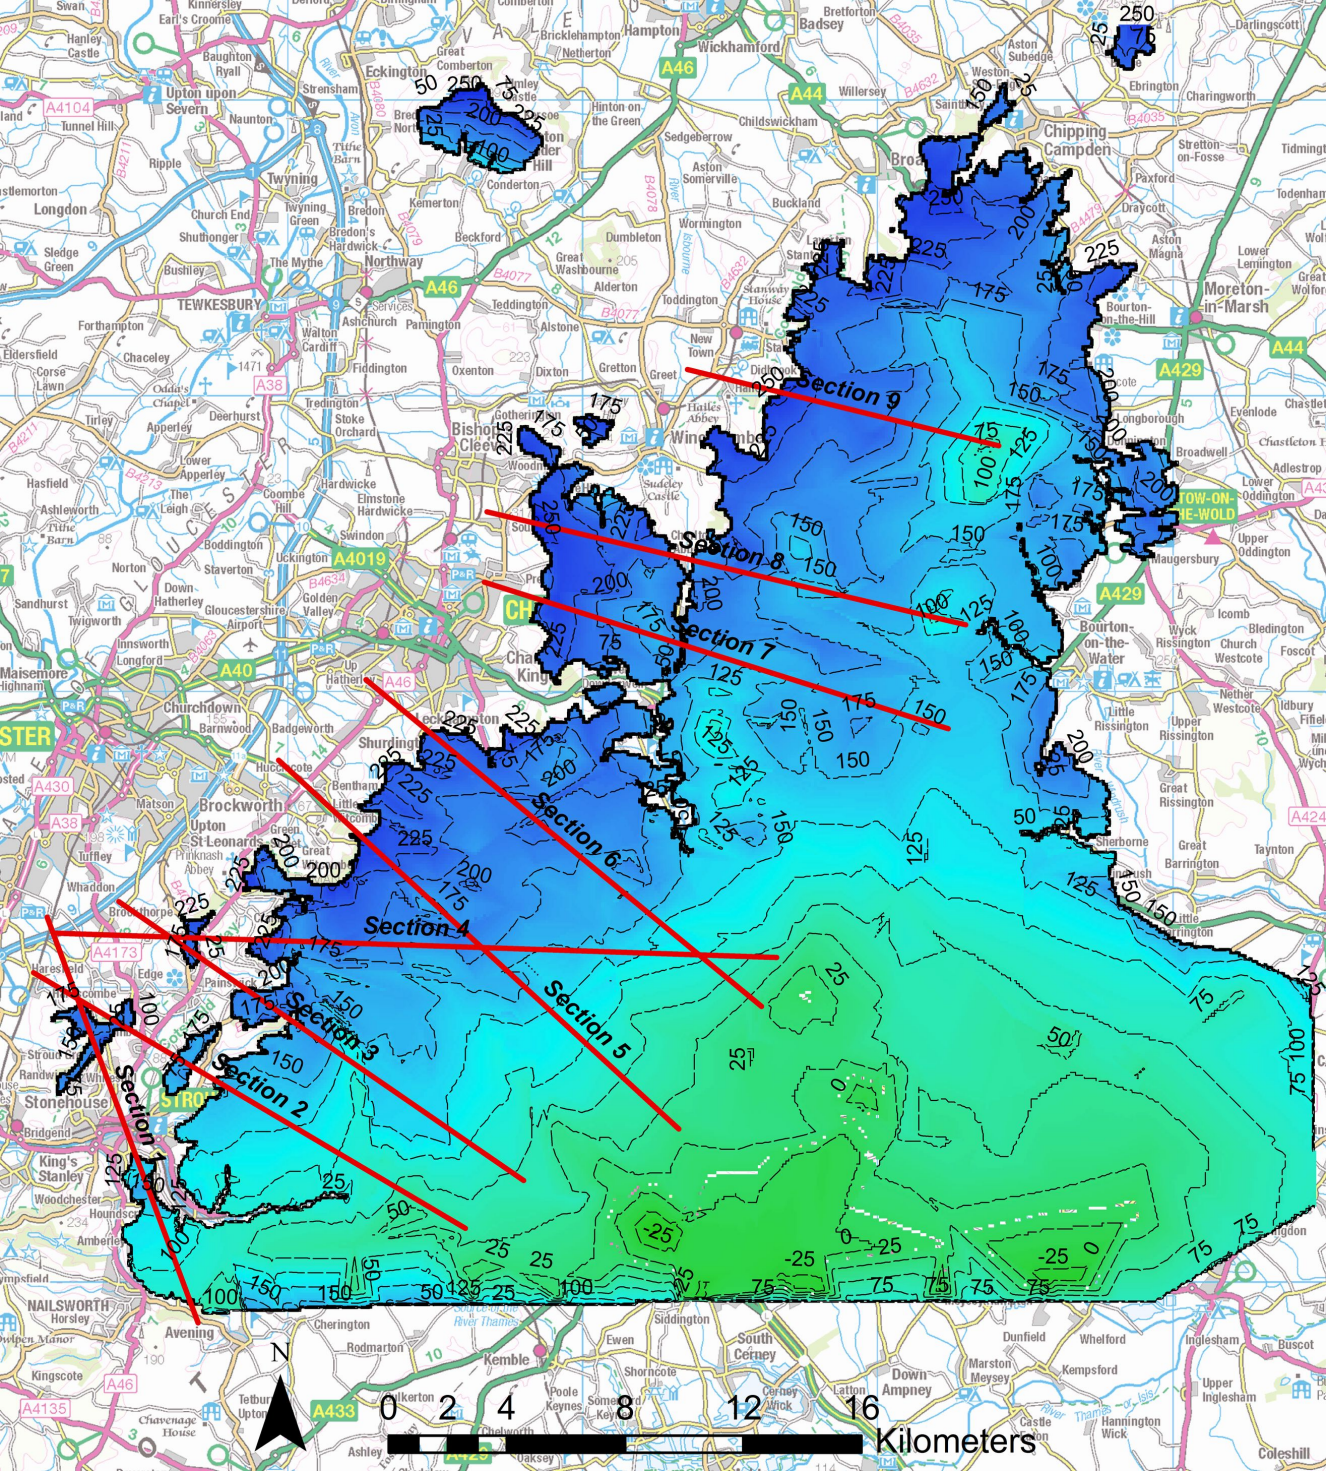

Gradual valley incision and concurrent widening by lateral channel migration and slope retreat at times $t=1$ to 4

B. Model 2.

Topography generated 'in-situ' by differential erosion of hard and soft lithologies beneath sub-Cretaceous unconformity at times $t=1$ to 4

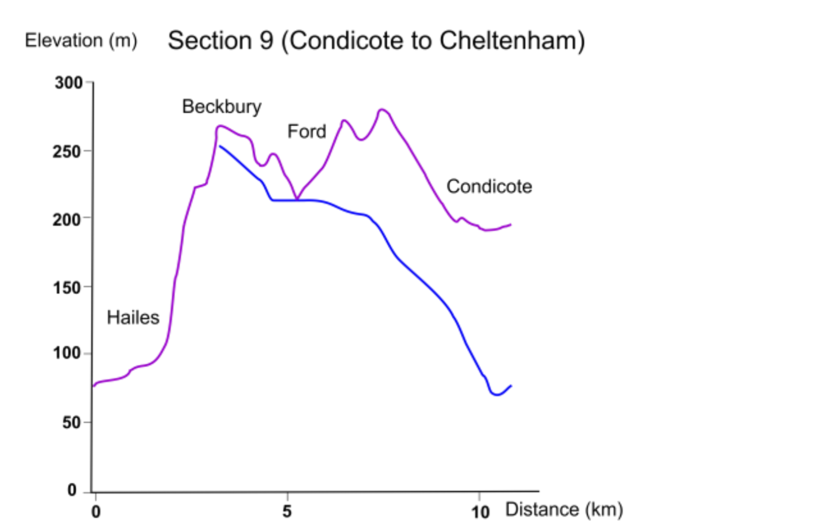

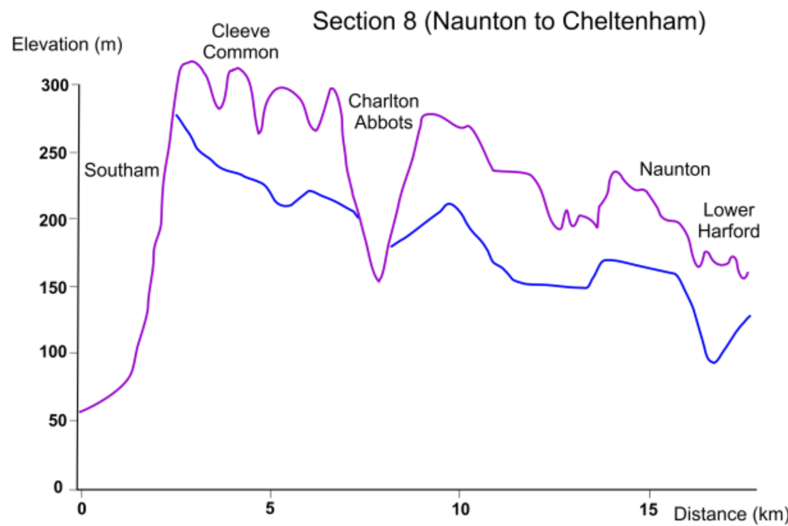

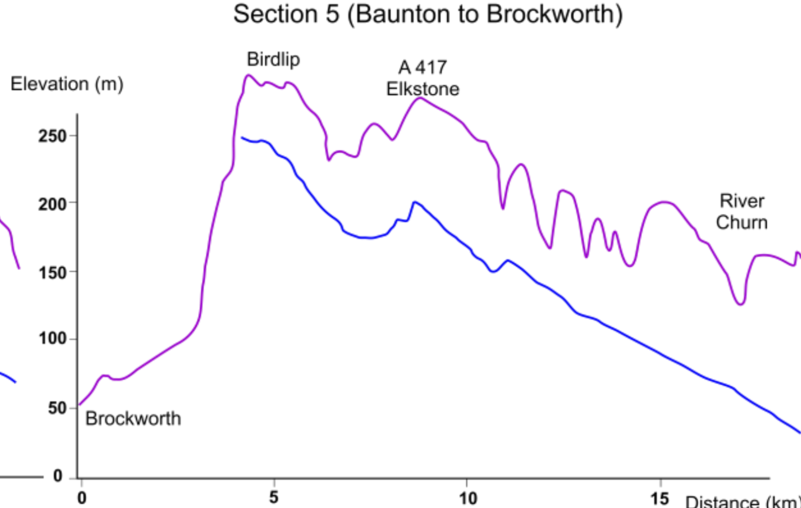

Table 1. Gull Caves speleothem U-Th isotope data

Sample	Concentration			Ratios Corrected for detrital Th			Age (ka, uncorr) [#]	Age (ka, corr) ^{#*}	$[^{234}\text{U}/^{238}\text{U}]_{\text{Initial}}^{\#*}$
