22 **ABSTRACT**

23 **Background.** *Neisseria meningitidis* is a frequent colonizer of the human nasopharynx with
24 asymptomatic carriage providing the reservoir for invasive, disease-causing strains. Serogroup Y
25 (MenY) strains are a major cause of meningococcal disease. High resolution genetic analyses of
26 carriage and disease isolates can establish epidemiological relationships and identify potential
27 virulence factors.

28 **Methods.** Whole genome sequence data were obtained from UK MenY carriage isolates from
29 1997-2010 (n=99). Sequences were compared to those from MenY invasive isolates from 2010
30 and 2011 (n=73) using a gene-by-gene approach.

31 **Results.** Comparisons across 1,605 core genes resolved 91% of isolates into one of eight clusters
32 containing closely related disease and carriage isolates. Six clusters contained carried
33 meningococci isolated in 1997-2001 suggesting temporal stability. One cluster of isolates,
34 predominately sharing the designation Y: P1.5-1,10-1: F4-1: ST-1655 (cc23), was resolved into a
35 sub-cluster with 86% carriage isolates and a second with 90% invasive isolates. These sub-
36 clusters were defined by specific allelic differences in five core genes encoding glycerate kinase
37 (*glxK*), valine-pyruvate transaminase (*avtA*), superoxide dismutase (*sodB*) and two hypothetical
38 proteins.

39 **Conclusions.** High resolution genetic analyses detected long-term temporal stability and
40 temporally-overlapping carriage and disease populations for MenY clones but also evidence of a
41 disease-associated clone.

42

43 **Keywords:** *Neisseria meningitidis*; whole genome sequencing; carriage; serogroup Y;
44 epidemiology

45 **BACKGROUND**

46 *Neisseria meningitidis* is carried in the nasopharynx of 10 to 30% of the population with carriage
47 rates influenced by setting and generally higher in young adults and close contact populations [1,
48 2]. Occasionally, meningococci invade, resulting in meningococemia and meningitis. Invasive
49 meningococcal disease (IMD) results in substantial mortality and morbidity despite effective
50 antibiotic treatment [3].

51 A key virulence factor is the polysaccharide capsule, which allows the bacterium to resist
52 complement-mediated lysis and opsonophagocytosis [4]. Twelve serogroups are recognized [5],
53 but only six, A, B, C, W, X and Y are responsible for the majority of disease worldwide [6].
54 DNA sequence-based approaches have been extensively applied to the analysis of the population
55 structure of meningococci [7]. Multilocus sequence typing (MLST), using sequences of seven
56 representative housekeeping genes, has demonstrated a highly structured population, with most
57 strains belonging to groups of closely related genotypes referred to as clonal complexes (ccs) [8].
58 Some of these clonal complexes correspond to ‘hyperinvasive lineages’, which are responsible
59 for most cases of disease worldwide [9, 10]. These clonal complexes are often associated with
60 specific combinations of antigenic proteins, such as Porin A (PorA) and Ferric enterobactin
61 transport protein A (FetA), and serogroups [11, 12].

62 Much of the IMD in Europe and North America is caused by a limited range of
63 serogroup/genotype combinations, for example serogroup B (MenB) ST-41/44, ST-32 and ST-
64 269 isolates and serogroup C (MenC) isolates from ST-11 and ST-8 complexes [6, 13]; however,
65 in recent decades the incidence of IMD due to MenY organisms, often belonging to cc23, has
66 increased in several countries, including the USA, Sweden, and the United Kingdom [14-18]. In
67 the UK, several carriage studies performed between 2008 and 2012 detected evidence of recent

68 alterations in MenY carriage epidemiology in young adults [19-22]. For example, MenY
69 meningococci were found in only 1-2% of participants and constituted only *ca.* 10% of
70 recovered isolates when carriage was assessed in 1997-8 in first-year university students at the
71 University of Nottingham, UK and during 1999-2001 in >48,000 15-17 year-old school students
72 throughout the UK [23, 24]. In contrast, in 2008-9 and 2009-10, significantly higher rates of
73 overall carriage, principally resulting from the high prevalence of MenY strains, were detected in
74 university students in Nottingham [19, 20]. These observations were supported by subsequent
75 multisite studies undertaken to investigate carriage in UK school and university students [21,
76 22]. Identification of isolates in the 2008-9 and 2009-10 Nottingham carriage studies relied on
77 PCR amplification of capsule genes and, while some further typing information was generated
78 for a subset of the 2008-9 isolates [19], only limited information was available on the numbers
79 and genetic background of the different MenY-associated clonal complexes carried in 2009-10.

80 High resolution analyses of genome-wide genetic relationships can determine the
81 prevalence of disease-causing isolates among collections of carriage isolates and detect specific
82 disease-associated loci. The PubMLST.org/neisseria database, which employs the Bacterial
83 Isolate Genome Sequence database (BIGSdb) platform, is a scalable, open-source web-accessible
84 database, to identify, index and extract genetic variation data from whole genome sequence
85 (WGS) data [25]. This approach was utilized to resolve an outbreak of ST-11 disease [26], to
86 investigate the evolution and global spread of the ET-5/ST-32 lineage [27], and to describe
87 MenY disease isolates in Sweden [28]. Additionally, a genealogical analysis of 108
88 representative meningococcal genomes led to the proposal of a new lineage nomenclature
89 reflecting the increased resolution of WGS typing compared to MLST [29].

90 Here we investigated the population structure of MenY invasive and carriage isolates in
91 the UK using WGS data generated from 99 carriage isolates obtained from school or university
92 students (typically 16 to 20 years old) between 1997 and 2010 and compared these genomic data
93 with 73 publically available genomes from invasive MenY strains isolated in 2010-11.

94

95 **METHODS**

96 **Isolates**

97 A total of 99 MenY isolates, all obtained from nasopharyngeal carriers in Nottingham (East
98 Midlands), UK, were included in the WGS analysis (Supplementary Table 1). Of these, 77 were
99 isolated from students attending the University of Nottingham in 2009 [20] and were chosen as
100 follows: (i) 20 obtained in September 2009 from first-year students; (ii) 18 obtained in
101 September 2009 from second-year students; (iii) 19 obtained in December 2009 from first-year
102 students; (iv) 20 obtained in December 2009 from second-year students [20]. To provide context,
103 10 isolates were chosen randomly from a collection of MenY meningococci isolated from sixth-
104 form school students in Nottingham in 1999-2001 [24] and six isolates were chosen from MenY
105 carried isolates obtained from first-year students at the University of Nottingham during 1997-8
106 [23]. All of these isolates were chosen as known MenY organisms based on PCR or serological
107 typing methods, without prior knowledge of their clonal complex. Six additional MenY carriage
108 isolates were chosen as representative examples of the predominant MenY lineages circulating in
109 a 2008-9 cohort of first-year students at the University of Nottingham [19].

110

111 **Genomic DNA Extraction, Illumina Sequencing, Assembly and Deposition**

112 Meningococci were grown overnight on heated horse-blood ('chocolate') agar (Oxoid) at 37°C
113 in an atmosphere of air plus 5% CO₂ and genomic DNA extracted using the Wizard Genomic
114 DNA Purification Kit (Promega). Genomic DNA was sequenced as described previously [29].
115 Short-read sequences were assembled using the VelvetOptimiser de novo short-read assembly
116 program optimization script after which resultant contiguous sequences (contigs) were uploaded
117 to the PubMLST.org/neisseria database. Sequence reads were deposited in the European
118 Nucleotide Archive (Supplementary Table 1). Genome sequences of the 73 MenY disease
119 isolates for the epidemiological year 2010-11 in England, Wales and Northern Ireland
120 (Supplementary Table 2) were accessed via the Meningitis Research Foundation Meningococcus
121 Genome Library database
122 (http://pubmlst.org/perl/bigfdb/bigfdb.pl?db=pubmlst_neisseria_mrfgenomes; accessed
123 September 2015).

124

125 **Genomic Analyses**

126 The genome assemblies deposited in the database are automatically curated and annotated for all
127 loci currently defined in the database thus identifying alleles with $\geq 98\%$ sequence identity. Over
128 2,600 loci were defined at the time of analysis. These have a 'NEIS' prefix and are organized
129 into schemes which enables, for example, the rapid identification of isolate genogroup, clonal
130 complex, and PorA and FetA antigen types. Further analysis was undertaken using the BIGSdb
131 Genome Comparator tool implemented within the database using the *N. meningitidis* cgMLST
132 v1.0 core genome scheme (1,605 loci) [29]. Output distance matrices (Nexus format) were used
133 to generate NeighborNet graphs with SplitsTree4 (v4.13.1).

134

135 **RESULTS**

136 **General Features of Sequenced MenY Carriage Genomes**

137 After de novo assembly, the 100-bp paired Illumina reads from the 99 MenY carriage isolates
138 produced contiguous sequences between 2,018,731 bp to 2,214,168 bp in size, consistent with
139 expectations for meningococcal genomes (Supplementary Table 1). Genome assemblies were
140 automatically annotated in a 'gene-by-gene' approach using the BIGSdb platform and strain
141 designation data extracted (Supplementary Table 1). Isolates from cc23 predominated (58%),
142 followed by cc174 (18%), cc167 (11%) and cc22 (7%). The most prevalent strain designations
143 were Y: P1.5-1,10-1: F4-1: ST-1655 (cc23), Y: P1.5-1,2-2: F5-8: ST-23 (cc23) and Y: P1.21,16:
144 F3-7: ST-1466 (cc174), which collectively accounted for 48% of the carriage isolates (Table 1).
145 Of the 16 carriage strains isolated in 1997-2001, 11 shared identical strain designations with
146 2008-10 carriage isolates suggesting persistence of these strain designations over this 7-13 year
147 time period (Table 1).

148 To investigate the occurrence of these carriage strain designations amongst invasive
149 MenY isolates, identical typing information was extracted from the WGS data of 73 invasive UK
150 MenY meningococci isolated during 2010-11 available via the MRF Meningococcus Genome
151 Library database (Supplementary Table 2). Isolates from cc23 predominated (79%), followed by
152 cc174 (10%), cc167 (5%) and cc22 (3%). The most prevalent strain designations among the
153 invasive isolates matched those found in the carriage collection (Table 1). Ten designations were
154 present in both carriage and invasive isolates: these designations accounted for 74% of carriage
155 and 73% of invasive isolates, respectively (Table 1).

156

157 **WGS Analysis of MenY Isolates Identifies Clusters of Highly Related Isolates**

158 To allow higher resolution genealogical analyses, comparison of all 172 MenY genomes was
159 undertaken using the BIGSdb Genome Comparator tool, the principal output of which is a
160 distance matrix based on the number of variable loci within those loci selected for analysis, these
161 differences were then resolved into a network using standard algorithms [30]. Comparison of the
162 genomes using the core *N. meningitidis* cgMLST v1.0 scheme [29] identified 1,157 loci which
163 varied in at least one isolate and resolved isolates into two distinct groups comprising 56 and 116
164 isolates, respectively (Figure 1). Only thirteen loci were found to be identical between these two
165 groups: these included loci encoding ribosomal and hypothetical proteins. Within the two groups,
166 distinct clusters of isolates containing multiple examples of both carriage and invasive isolates
167 were evident. Group 1 comprised three clusters, containing isolates belonging to cc167, cc22 and
168 cc174. Group 2 contained only cc23 meningococci, which formed five distinct clusters of
169 carriage and invasive organisms (Figure 1). Overall 91% (157/172) of isolates localized to one of
170 these eight clusters.

171

172 **Relationships Between Invasive and Carriage MenY Isolates in Identified Clusters**

173 To visualize the relationships among closely related isolates, NeighborNet graphs were generated
174 for each cluster with color-coding of isolate names detailing provenance (Figures 2, 3 and 4).
175 Amongst the 25 isolates in the cc174 cluster (Figure 2A), evidence of extensive genetic
176 similarities between carriage isolates was apparent with, for example, only 6 allelic differences
177 distinguishing isolates 22014 and 23214. Highly-related 2009-10 carriage isolates were often
178 isolated from students in the same year group suggestive of intra-year group transmission. This
179 was also apparent in other clusters of isolates, such as cc22 (*e.g.* isolates 22667 and 21258; 8
180 allelic differences) (Figure 2C). Conversely, the cc22 cluster revealed highly related

181 meningococci isolated from individuals in different year groups suggestive of inter-year group
182 transmission (*e.g.* isolates 23009 and 21513; 3 allelic differences) (Figure 2C).

183 The cc167 cluster (Figure 2B) and cc23 cluster 4 (Figure 3D) each resolved into distinct
184 sub-clusters. The ST-767 cc167 sub-cluster (Figure 2B) contained carriage isolates from 2001,
185 2008 and 2009 and a 2011 invasive isolate (M11 240071), suggestive of a long-lived clone
186 capable of causing disease. Only 27 allelic differences distinguished M11 240071 from N117.1;
187 62 differences distinguished the former from NO01020675 – a carriage isolate obtained in 2001
188 (Figure 2B).

189 In some cases, clusters containing isolates with identical designations could also be
190 resolved into distinct sub-clusters on the basis of WGS analysis. Notably, cc23 cluster 1 could be
191 resolved into two sub-clusters (Figure 3A). The first contained a carriage isolate from 2000
192 (NO0010442), five 2008-10 carriage isolates and two 2010-11 invasive isolates. Since
193 NO0010442 is only 34 allelic differences apart from 21251 (a 2009 carriage isolate) and 42 from
194 the invasive isolate M10 240732, this sub-cluster represents another persistent clone, capable of
195 causing disease.

196

197 **WGS Analysis Resolves cc23 Cluster 5 into Invasive- and Carriage-Associated Sub-clusters**

198 The cc23 cluster 5 contained the largest number of MenY isolates analyzed. Despite
199 predominantly sharing a common strain designation, WGS-based analysis resolved
200 meningococci in this cluster into two sub-clusters (Figure 4): sub-cluster 1 with 18 carriage
201 isolates and three invasive isolates; and sub-cluster 2 with three carriage and 27 invasive
202 meningococci. A total of 997 loci were identical among all cc23 cluster 5 isolates. These sub-
203 clusters were defined by specific allelic differences in five core genes, encoding glycerate kinase

204 (*glxK*), valine-pyruvate transaminase (*avtA*), superoxide dismutase (*sodB*) and two hypothetical
205 proteins (Table 2).

206

207 **DISCUSSION**

208 Nucleotide sequence-based methods involving small numbers of genes have been invaluable in
209 characterizing the population structure and antigenic repertoires of meningococci [31]. The
210 advent of WGS has greatly enhanced resolution and has begun to provide improved insights into
211 the genetic relationships among bacterial isolates [32]. Since carriage is directly relevant to the
212 epidemiology of IMD, we undertook to resolve the genealogical relationships between carriage
213 and invasive isolates. We focused on MenY lineages due to recent observations of fluctuations in
214 MenY disease and carriage levels in the UK. Although meningococci of this serogroup have
215 been less prevalent globally as causes of disease compared to serogroups A, B and C [33], the
216 proportion of IMD attributable to MenY organisms, predominately those belonging to cc23,
217 increased markedly, a trend first recognized in the mid-1990s in the USA [14, 34], and more
218 recently in other countries including the UK [17, 18] and Sweden [15, 35]. The higher MenY
219 IMD case load in the UK was concomitant with a significant increase in MenY carriage, as first
220 detected in studies of nasopharyngeal carriage in students at the University of Nottingham
221 undertaken from 2008 to 2010 [19, 20].

222 The automated extraction of strain designation information from WGS data demonstrated
223 the similarity of MenY isolates from carriage and invasive disease. This similarity was
224 confirmed by the enhanced discrimination afforded by core genome analysis of the WGS data
225 which resolved most of the isolates into one of eight defined clusters. While most isolates in a
226 particular cluster shared the same strain designation (*i.e.* ST, PorA and FetA types), each cluster

227 contained variants, demonstrating the enhanced discrimination afforded by WGS. A key finding
228 was that every cluster contained both invasive and disease isolates, indicating that all MenY
229 lineages have the ability to cause disease.

230 Bacterial populations are often viewed as unstable collections of rapidly evolving clones
231 with frequent extinctions or replacement of older clones. Temporal shifts are potentially
232 important components of IMD epidemiology. Thus, analysis of IMD cases indicated replacement
233 of an 'early' cc23 MenY lineage in the USA by an antigenically and genetically distinct 'late'
234 strain type [36, 37]. A parallel shift in carriage of these clones was assumed but not investigated.
235 A significant finding from the present study was that six out of the eight MenY clusters
236 contained historic carriage isolates (*i.e.* from 1997-2001). The stability of this association
237 appears to be strong as it was detected with only sixteen historic genome sequences. Thus, these
238 six MenY clusters are long-lived and have been present within the UK for a 7-13 year time
239 period. The uneven distribution (*e.g.* cc167 and cc23 cluster 1) and apparent outlier position (*e.g.*
240 cc174 and cc22) of historic isolates in some clusters is suggestive of within-cluster evolution
241 over time. The exception to this generalization was cc23 cluster 5, which was the largest cluster
242 and yet contained no historic strain types, potentially suggesting the arrival of a non-UK
243 associated epidemic lineage or major alterations in the genetic structure of a long-lasting UK
244 MenY clone. The presence of long-lasting clones indicates that the genetic structure of
245 meningococcal clones is stable and that extinctions of clones are rare events. The presence of a
246 long-lived host-adapted commensal population has importance as introduction of the
247 MenACWY vaccine into the main carrier population has the potential to radically-perturb a long-
248 lasting association with unknown consequences.

249 There was evidence for antigenic shifts among members of the cc23 isolates, which
250 distributed into five clusters distinguished by PorA type but not ST type. Four of the clusters
251 differed in sequence for VR2 of PorA, a major target of bactericidal antibodies while the two
252 clusters with identical PorA VR2 sequences had different PorA VR1 sequences, a variable target
253 of bactericidal antibodies. The differences in the VR2 amino acid sequence are the increase in
254 number of a three amino acid motif (NKQ) from one copy in P1.10-1, to two in P1.10-4 and
255 three in P1.10-10: a rapid and minor change in protein structure. This was not a feature of all
256 surface antigens, as there was limited variation in the FetA VR with four cc23 clusters having the
257 same FetA variant. Further analysis of WGS data may indicate other antigenic variants or allelic
258 variants of other genes that correlate with this segregation of cc23 isolates; nevertheless the PorA
259 distribution suggests that minor differences in antigenicity may contribute to changes in
260 population structure.

261 Geographic distribution of clones and potential sources of new clones was apparent from
262 comparisons among WGS studies in different countries. Comparison of invasive cc23 isolates
263 from Sweden, UK and USA identified three principal cc23 sub-lineages (designated 23.1, 23.2
264 and 23.3) with overlapping, but differentially prevalent repertoires in each country [28]. For
265 example, the Swedish ‘strain-type YI’ which was largely responsible for the increase in Swedish
266 MenY disease [16, 35], formed a cluster within the 23.1 sub-lineage, but very rarely caused
267 disease in the UK [28]. Using the overlap in MenY WGS data analyzed, *i.e.* UK invasive cc23
268 strains isolated in 2010-11 examined previously [28], we further resolved the 23.1 sub-lineage
269 into four sub-clusters (cc23 clusters 2-5) and found that cc23 cluster 1 corresponds to lineage
270 23.2. Cluster 5, which was responsible for most cases of UK IMD, was rarely observed in
271 Swedish IMD isolates.

272 The resolution of cc23 cluster 5 into distinct carriage- and disease-associated sub-
273 clusters, (1 and 2, respectively) was surprising as this cluster contained the highest number of
274 MenY disease and carriage isolates. A confounding factor is that the sub-cluster 1 carriage
275 isolates were all isolated in one geographical location, and hence may have a high level of one
276 specific (highly transmissible) clone. Two of these isolates (20601 and 21619) were, however,
277 isolated in the first week of term in September from first-year students who are presumed to have
278 been colonized prior to arrival at the University. An alternative hypothesis is that the ability of
279 sub-cluster 1 strains to cause disease is associated with rapid within host evolution into a sub-
280 cluster 2 phenotype; however, sub-clusters were defined by differences in loci encoding proteins
281 with hypothetical or core enzymatic functions not loci explicitly linked to adaptation to a
282 systemic niche (*e.g.* survival in blood). A further possibility is that sub-cluster 1 has recently
283 evolved from sub-cluster 2 into a highly transmissible carriage strain with a consequent
284 reduction in virulence. It is unlikely that any of the five differences in sub-cluster 1 and 2
285 defining core loci are directly responsible for differences in virulence given the predicted
286 functions of the five proteins, and that the allelic differences lead to, at most, only single amino
287 acid changes which are unlikely to be functionally significant. Instead we hypothesize that
288 differences outside the core alleles examined in this study, but which will co-segregate with the
289 five core loci differences, are more likely to be responsible. A high-quality assembled cc23
290 genome is required to detect the effects on virulence mediated by non-core genes, and in order to
291 determine how the transition between these sub-clusters has occurred.

292 In summary, high resolution genealogical relationships between MenY isolates
293 highlighted the high degree of genetic similarity between carriage and invasive isolates and
294 evidenced long-term stability of MenY clones. The detection and resolution of a highly prevalent

295 UK clone (Y: P1.5-1,10-1: F4-1: ST-1655 cc23) into invasive- and carriage-associated sub-clusters
296 exemplifies the improved precision of whole genome analysis for separating apparently identical
297 isolates.

405

406 **FIGURE LEGENDS**

407 **Figure 1.** NeighborNet graph comparison of 172 UK MenY genome sequences analyzed using
408 the BIGSdb Genome Comparator utilizing the *N. meningitidis* cgMLST v1.0 scheme. 91% of
409 isolates analyzed localized to one of eight clusters. Strain designation(s) represent the most
410 frequently occurring designation(s) in each cluster. Unlabeled nodes represent unassigned
411 invasive (n=9) and carriage (n=6) isolates. Scale bar = number of allelic differences.

412

413 **Figure 2.** NeighborNet graphs comparing isolates in the (A) cc174, (B) cc167 and (C) cc22
414 clusters as defined in Figure 1. Sequences were analyzed using BIGSdb Genome Comparator
415 tool utilizing the *N. meningitidis* cgMLST v1.0 scheme. Isolate names are color-coded as
416 follows: 1997-2001 carriage isolates in fuchsia; 2008-9 carriage isolates in black; 2009-10
417 carriage isolates from first year students in green; 2009-10 carriage isolates from second year
418 students in blue and invasive isolates from 2010-11 in red. Scale bar = number of allelic
419 differences.

420

421 **Figure 3.** NeighborNet graphs comparing isolates in the cc23 cluster nos. 1, 2, 3 and 4 (panels A-
422 D, respectively) as defined in Figure 1. Sequences were analyzed using BIGSdb Genome
423 Comparator tool utilizing the *N. meningitidis* cgMLST v1.0 scheme. Isolate names are color-

424 coded according to the scheme described in the Figure 2 legend. Scale bar = number of allelic
425 differences.

426

427 **Figure 4.** NeighborNet graph comparison of isolates in the cc23 cluster 5 defined in Figure 1.

428 Sequences were analyzed using BIGSdb Genome Comparator tool utilizing the *N. meningitidis*

429 cgMLST v1.0 scheme. Isolate names are color-coded according to the scheme described in

430 Figure 2 legend. Scale bar = number of allelic differences.

431 **Table 1. Frequency of Strain Designations in the MenY Carriage and Invasive Collections**

Strain designation	Carriage group		Total carriage (n=99)	Invasive 2010-11 (n=73)	Total carriage and invasive (n=172)
	1997-2001 (n=16)	2008-10 (n=83)

^a UoN = University of Nottingham

^b Derived from genome sequence data.

^c Weighted median statistic indicating that 50% of the entire assembly is contained in contigs equal to, or larger than, this value.

SUPPLEMENTARY TABLE 2. Details of the 73 MenY invasive isolates used in this study. All were isolated during the epidemiological year 2010-11 in England, Wales and Northern Ireland. Further details can be found in the Meningitis Research Foundation Meningococcus Genome Library database.
